The use of antimotility agents (e.g., loperamide [Imodium] or dyphenoxylate and atropine [Lomotil]) in children younger than 2 years of age is not recommended. Because overdoses of these types of drugs can be fatal, they should be used with extreme caution in children. Side effects of these drugs in adults include opiate-induced ileus, drowsiness, and nausea. Lomotil has been associated with fatal overdoses and other severe complications, including coma and respiratory depression. Antinausea medications, such as promethazine and prochlorperazine, are not recommended routinely. They are contraindicated for use in children younger than 2 years. Fatal respiratory depression in children has been reported with use of promethazine. Children with an acute illness, including gastroenteritis and dehydration, are more susceptible than are adults to neuromuscular reactions, especially dystonias, associated with prochlorperazine. The extrapyramidal side effects associated with these medications can be confused with symptoms of other undiagnosed primary diseases associated with vomiting, such as Reye syndrome. These medications should not be prescribed routinely for empirical treatment of children with possible traveler's diarrhea. Adults traveling with children should be fully counseled about the indications, dosage, frequency, and possible side effects if these medications are prescribed.[53,95]

Antibiotics

Prophylactic antibiotics are not recommended for most travelers. Many clinicians will prescribe antibiotics to be administered as empirical self-treatment; however, few data are available for empirical administration of antibiotics for traveler's diarrhea in children. The antimicrobial options for empirical treatment in children are limited. Trimethoprim-sulfamethoxazole was used previously for empirical treatment of traveler's diarrhea in children; however, its effectiveness has been reduced by widespread drug resistance and it is no longer routinely recommended. Fluoroquinolones are used frequently for the empirical treatment of traveler's diarrhea in adults. The use of fluoroquinolones generally is not recommended in children and adolescents younger than 18 years of age because of cartilage damage in animals tested.[63] In children, the American Academy of Pediatrics suggests some special circumstances for fluoroquinolone use, including the treatment of gastrointestinal infection caused by multidrug-resistant *Shigella* spp., *Salmonella* spp., *Vibrio cholerae*, or *Campylobacter jejuni*.[62] However, the routine use of fluoroquinolones for chemoprophylaxis or empirical treatment for traveler's diarrhea (TD) among young children is not recommended. For young adults ages 19 and older, the fluoroquinolones are generally prescribed as 1- to 3-day regimens. Clinicians should be aware that fluoroquinolone resistance in gastrointestinal organisms has been reported from some countries, particularly in Southeast Asia.

In some studies, azithromycin has been found to be as effective as fluoroquinolones in treating traveler's diarrhea in adults.[1] In practice, some clinicians prescribe azithromycin either as a single dose or at 10 mg/kg for 3 days for empirical treatment for children. Flavored oral suspension of azithromycin is available. The suspension does not require refrigeration; however, it should be used within 10 days of mixing. The unreconstituted form of azithromycin has a longer expiration period. In certain circumstances, the unreconstituted form can be provided with clear instructions for preparation and may be useful for children traveling for more than 10 days.

PREVENTION OF OTHER INFECTIOUS DISEASES IN PEDIATRIC TRAVELERS

Because the epidemiology of many diseases is evolving, prevention hinges on the clinician being knowledgeable about information on current outbreaks and risk in planned travel destinations, evaluating risk based on planned activities and the season of travel, and providing appropriate counseling and vaccination, if available. Information about specific infectious disease risks can be obtained from numerous sources listed in the section on international travel information resources. More detailed information about specific vaccinations is included in the section on vaccination for international travel.

A variety of pathogens increasingly are being recognized as emerging infectious diseases in travelers. In addition to malaria, other vector-borne infectious diseases are among the important diseases for consideration in travelers. Dengue is one of the most significant vector-borne viral infections worldwide. It is endemic in at least 100 countries in Asia, the Pacific, Africa, Latin America, and the Caribbean and occurs sporadically in the Middle East. Worldwide, an estimated 50 to 100 million cases of dengue fever occur annually, including 500,000 dengue hemorrhagic fever cases and 22,000 deaths, mostly among children.[15] Dengue fever has been reported among 2 to 14 percent of ill travelers.[10,74,117,145] Epidemics of dengue hemorrhagic fever, the more severe clinical form of dengue fever, occur every 3 to 5 years in Southeast Asia and are an emerging problem in Latin America.[118] Epidemics caused by all four serotypes (1 to 4) have become progressively more frequent and larger in the past 25 years. In addition, most tropical urban centers in endemic regions have multiple dengue virus serotypes co-circulating (hyperendemicity), which increases the risk for dengue transmission and the risk for dengue hemorrhagic fever.[52] Outbreaks of dengue fever also have occurred in Hawaii, Puerto Rico, the U.S. Virgin Islands, Samoa, Guam, and along the United States–Mexican border.[15,18,19,124] In a recent short report by Krishnan and associates,[96] eight children were diagnosed with dengue between 2007 and 2010 at Bronx-Lebanon Hospital Center in New York City. The cases had a median age of 13.6 years (range, 0.3 to 17.6 years). All of the children were visiting friends and relatives in Puerto Rico (12%) or the Dominican Republic (88%). Of the eight children, three (38%) developed complications, including dengue shock syndrome in one infant.[96] Dengue is transmitted primarily by day-biting *Aedes aegypti* mosquitoes, which breed in flower vases, barrels, and discarded tires that collect water. Transmission occurs in rural and urban areas, but the risk is greatest in urban areas. Prevention should focus on protection against mosquito bites. Travelers to areas of risk should be counseled to apply repellent during the day, even while visiting cities. No vaccine is available, and previous infection with one of the four serotypes does not protect against infection with another serotype. The risk for contracting dengue hemorrhagic fever increases after subsequent infection with a different serotype.[135]

Avian influenza A (H5N1) has become a panzoonotic infection affecting regions of Asia, Africa, and the Middle East. Between 2003 and July 6, 2012, the WHO reported 607 human cases and 358 deaths caused by avian influenza from 15 countries, primarily from Indonesia, Vietnam, Egypt, China, Cambodia, and Thailand. Most of these cases were associated with direct contact with infected poultry.[20,155] Risk to travelers is low. However, clinicians should obtain up-to-date information about affected countries and counsel travelers going to those areas. Persons visiting areas with reports of outbreaks of H5N1 among poultry or of human H5N1 cases can reduce their risk for infection by (1) avoiding direct contact with poultry, including touching well-appearing, sick, or dead chickens; (2) avoiding poultry farms and bird markets; (3) avoiding handling surfaces contaminated with poultry feces or secretions; (4) practicing frequent and careful hand washing; and (5) consuming all foods from poultry, including eggs and poultry blood, only if they have been thoroughly cooked. Because influenza

viruses are destroyed by heat, the cooking temperature for poultry meat should be 74° C (165° F).[20]

Chikungunya virus is an alphavirus that exists in tropical Africa and is transmitted by the bite of infected mosquitoes. Because chikungunya fever epidemics are sustained by human-mosquito-human transmission, the epidemic cycle is similar to those of dengue and urban yellow fever. Infection is associated with fever, headache, severe joint pain, and, in approximately half of the cases, a generalized maculopapular rash similar to that of dengue virus infection. Complications are more common in children younger than 1 year of age. Large outbreaks of chikungunya have been reported recently on several islands in the Indian Ocean and in India. During 2005 to 2006, 12 cases were reported in travelers who arrived in the United States from areas known to be epidemic or endemic for chikungunya virus.[39,75,132] No vaccines or specific preventive medications are available; therefore, prevention measures should focus on personal protection against mosquito bites and awareness of local epidemics.[39]

African trypanosomiasis (sleeping sickness), a parasitic infection transmitted by the bite of a tsetse fly, occasionally has been reported in travelers, including children. Infection can result in severe neurologic sequelae and is 100 percent fatal if untreated.[17] Infection is caused by two species of *Trypanosoma brucei: T. brucei rhodesiense*, which is found in eastern and southeastern Africa (primarily Tanzania, Uganda, Malawi, and Zambia) and *T. brucei gambiense*, which is found predominantly in central Africa and limited areas of West Africa. Most infections in U.S. residents are caused by *T. brucei rhodesiense* and occur among travelers to East Africa game parks. In 2001, significant increases in cases were reported among U.S. and European travelers to game parks in Tanzania and Kenya. Between 1967 and 2000, an imported case occurred on average every 1 to 2 years; however, in 2001, seven cases were reported in U.S. travelers.[11,34,70,71,110-113] Travelers should use insect repellent and long-sleeved clothing in neutral colors of medium-weight material, because tsetse flies are attracted to bright or dark clothes and they can bite through lightweight clothing.[53]

Schistosomiasis, another parasitic infection caused by flukes that live part of their life cycle in fresh-water snail hosts, affects more than 200 million people worldwide. Schistosomiasis has been reported in travelers to endemic areas of Africa, Asia, South America, and the Caribbean who participated in high-risk activities such as swimming and wading in fresh water.[53,58,59,63] Most travel-associated infections occur among travelers to sub-Saharan Africa. Because most acute infections are asymptomatic, preventive counseling is critical. While in schistosomiasis-endemic areas, children should not swim in fresh, unchlorinated water such as lakes or ponds.[53]

More than 9 million new tuberculosis (TB) cases and 2 million TB-related deaths occur annually worldwide. A rate of tuberculin skin test seroconversion of 1.8 percent was reported among travelers to areas endemic for TB.[61] Of 357 travelers to the Hajj for pilgrimage, 10 percent had evidence of seroconversion when tested with use of QuantiFERON, a whole-blood assay for TB antigens.[146] Multidrug-resistant TB has been increasing in incidence worldwide. Cases of extensively drug-resistant TB have been reported from several countries, including Estonia, Latvia, Lesotho, Peru, the Philippines, South Africa, Swaziland, and the United States.[151,152] Travelers who may have prolonged exposure to TB should have two-step tuberculin skin test (TST) or a single interferon-γ release assay (IGRA), either the QuantiFERON TB test (Gold or Gold In-Tube versions) or T-SPOT TB test, before leaving the United States. If the predeparture test is negative, a single TST or IGRA should be repeated 8 to 10 weeks after returning from travel. IGRA is preferred for children who have received BCG vaccine.[53] According to reports, U.S. children who had traveled to countries with a high prevalence of TB within the previous 12 months were 3.9 times more likely to have positive tuberculin skin test results than were children who lived in the same U.S. areas but had not traveled.[102] Bacille Calmette-Guérin (BCG) vaccine is a live vaccine prepared from attenuated strains of *Mycobacterium bovis;* BCG is used primarily in young infants to prevent disseminated and other forms of life-threatening disease caused by TB, such as tuberculous meningitis. BCG is recommended by the WHO for administration at birth. Vaccination of a young pediatric traveler (non–HIV infected and with a negative tuberculin skin test response) might be considered if long-term stay (e.g., children of missionaries or expatriates) is planned in a country with a high prevalence of TB, particularly multidrug-resistant or extensively drug-resistant TB, and prolonged contact with persons with active TB is thought to be a potential problem.[2,3,121] BCG vaccine can be obtained from the Canadian subdivisions of Sanofi Pasteur.*

Tick-borne encephalitis is transmitted primarily by the bite of *Ixodes* ticks. It also can be transmitted by the ingestion of unpasteurized dairy products from infected livestock. Transmission occurs during the summer months in western and central Europe, Scandinavia, and parts of the former Soviet Union. Russia has the highest incidence. Most cases occur from April through November, when ticks are most active.[53] Travelers to affected areas should use measures to avoid tick bites and avoid consuming unpasteurized dairy products. Persons who will be traveling for longer than 3 weeks in endemic rural areas or travelers who will be engaging in high-risk activities, such as camping, should be considered for vaccination. The vaccine is not available in the United States but can be obtained in Europe and Canada.[53]

Adventure travel can increase the risk for acquiring a variety of infectious diseases. Examples of recent outbreaks or cases of unusual pathogens affecting adventure travelers include fungal organisms (e.g., histoplasmosis and coccidioidomycosis), leptospirosis, and leishmaniasis. Histoplasmosis is a fungal infection acquired by the inhalation of spores, usually through exposure to bat, bird, or chicken droppings in barnyards and caves. The organism is endemic in the United States, Latin America, eastern Asia, parts of Europe, Africa, and Australia. Coccidioidomycosis, a fungal infection associated with the inhalation of organisms in soil from high-risk areas, is

*Sanofi Pasteur: http://www.sanofipasteur.ca.

endemic in the southwestern part of the United States and Latin America. Both infections can cause a spectrum of illness from asymptomatic infection to acute pulmonary infection to severe, disseminated disease, especially in immunocompromised persons. Several outbreaks of histoplasmosis have been reported in groups of U.S. visitors who entered a cave with bats in Costa Rica,[22] Ecuador,[138,153] Peru,[14] and Nicaragua.[144] More than 200 college students became infected with histoplasmosis during a spring break trip to Acapulco, Mexico.[34,120,156] Two outbreaks of coccidioidomycosis have been reported in youth missionary groups involved in construction work in Mexico.[13,25] Most of these fungal outbreaks have two common features: high-risk group activities and high attack rates, even in young, nonimmunocompromised individuals. Because no vaccine is available, prevention involves counseling travelers to avoid exposure or to use special masks for high-risk individuals who cannot avoid exposure.[23]

Leptospirosis is a zoonotic infection transmitted by exposure to water or soil contaminated with organisms excreted by domestic and wild animals. Outbreaks have been reported in white-water rafters in Costa Rica[24] and in athletes from 26 countries who participated in the Eco-Challenge multisport expedition race in Borneo, Malaysia, in 2000.[27,31] Because no vaccine against leptospirosis exists, persons engaging in high-risk activities with exposure to recreational water activities or exposure to contaminated surface waters and soil should be counseled to avoid exposure to water that may be contaminated or to wear protective clothing, especially footwear, and to cover cuts and abrasions with occlusive dressings. They should avoid contact with, submersion in, or swallowing potentially contaminated water. The CDC recommends that persons engaging in high-risk activities consider the use of doxycycline (200 mg orally, once per week), begun 1 to 2 days before exposure and continuing through the period of exposure for prophylaxis; doxycycline should not be used routinely for children younger than 8 years of age.[53] Travelers at increased risk for leptospirosis and in need of malaria chemoprophylaxis should consider using doxycycline for both indications.

Leishmaniasis, a parasitic infection transmitted by the bite of a sandfly, can lead to cutaneous or visceral infection. It has been reported in students who traveled to the rain forest in Costa Rica and other travelers.[81,83,109,148] The appropriate use of insect repellent and other personal protection measures against sandfly bites is the only prevention tool available.

Finally, studies of sexual practices among travelers have shown that 5 to 50 percent of short-term travelers engage in casual sex while abroad; 40 to 60 percent of long-term travelers have reported engaging in casual sex while abroad.[107,125,126] A study of British travelers reported that 18.6 percent had had new sexual partners, two thirds of those who were sexually active did not use condoms on every occasion, and 5.7 percent contracted STDs.[133] Adolescents should be counseled about the risks for and prevention of STDs, hepatitis B, and HIV infection associated with sexual contact, sharing needles, or receiving acupuncture or tattoos.

GENERAL TRAVEL HEALTH COUNSELING FOR CHILDREN

During the pretravel assessment, the clinician should provide the parents with general advice and preventive counseling to avoid health risks and injuries in children. Simple personal protection measures can prevent children from incurring many types of travel-associated injuries and conditions. One of the most common skin conditions reported by travelers is sunburn. To prevent sunburn and the subsequent risk for skin malignant neoplasms later in life, children should avoid sun exposure during peak hours and use sunscreen appropriate for the child's age. When sunscreen and insect repellent are used concomitantly, the sunscreen should be applied first. There is no evidence that air travel exacerbates the symptoms or complications associated with otitis media.[65] Travel to different time zones, "jet lag," and schedule disruptions can disturb sleep patterns in infants and children, as well as adults.[53]

Motor vehicle accidents, injuries, and drownings pose a great risk for morbidity and mortality among international travelers.[53,125] Vehicle-related accidents are the leading cause of death in children who travel. While traveling in automobiles and other vehicles, children less than 4 feet 9 inches in height should be restrained in age-appropriate car seats or booster seats, as described earlier. In general, children are safest traveling in the rear seat; no one should ever travel in the bed of a pickup truck. Families should be counseled that in many developing countries, cars may lack front or rear seatbelts. Parents traveling with infants or young children should be advised to bring their own child safety restraint seats for use during travel. Night driving can be more hazardous, especially outside urban areas in developing countries, and should be avoided.[53] Use of a helmet is imperative for bicycle travel. Fire injuries can be prevented by advising parents to inquire whether hotels have smoke detectors and sprinkler systems (they also may consider bringing their own smoke detector). Conditions at hotels and other lodging may not be as safe as those in the United States, and accommodations should be carefully inspected for exposed wiring, pest poisons, paint chips, or inadequate stairway or balcony railings.[53] Drowning is the second leading cause of death in young travelers. Children may not be familiar with hazards in the ocean or in rivers. Swimming pools may not have protective fencing to keep toddlers from falling into the pool. Close supervision of children around water is essential. Appropriate water-safety devices such as life vests may not be available abroad, and families should consider bringing these from home. Parents and children participating in boating activities should be counseled to be aware of weather conditions and forecasts, and parents should be advised that an adult should accompany children at all times when swimming. Personal floatation devices should be used when boating or water-skiing, regardless of the distance to be traveled or swimming ability.[129] Swimming in contaminated water can result in skin, eye, ear, and some intestinal infections; for prevention of infectious diseases, generally only pools that

contain chlorinated water can be considered safe. Parents also should be advised that swimming in fresh-water lakes and streams in developing countries carries a risk for contracting schistosomiasis, leptospirosis, and primary amebic meningoencephalitis.[53] In salt-water bodies, biting and stinging fish, corals, and jellyfish also can be a risk. In general, children should wear covered footwear rather than sandals, including when wading on reefs and swimming.[53,129] Children should avoid walking barefoot, particularly in rural areas, to prevent cutaneous larva migrans, hookworm, and *Strongyloides* infections. Children are more likely than adults to have contact with soil or sand, and therefore they may be exposed to diseases caused by infectious stages of parasites present in soil, including ascariasis, hookworm infestation, cutaneous or visceral larva migrans, trichuriasis, and strongyloidiasis. Children and infants should wear protective footwear and play on a sheet or towel rather than directly on the ground. Clothing should not be dried on the ground. When traveling in countries with a tropical climate, clothing or diapers dried in the open air should be ironed before use to prevent infestation with fly larvae. Parents of pediatric travelers, especially to areas endemic for rabies, should be reminded to warn children that they should not attempt to pet, handle, or feed domestic or wild animals (including monkeys). Travelers also should avoid snakes because most bites are the direct result of handling, harassing, or trying to kill snakes.[53]

Travelers to high-altitude destinations should be counseled about the risk and prevention of altitude illness, including acute mountain sickness, high-altitude cerebral edema, and high-altitude pulmonary edema. Altitude sickness generally occurs at 2500 to 2700 m (8000 to 9000 ft), and acclimatization generally takes 3 to 5 days. Susceptibility and resistance are genetic traits, and no screening tests are available to predict risk. Children are equally susceptible as adults. Travelers to high-altitude destinations should be advised to ascend gradually, if possible, and those travelers going to destinations higher than 8000 to 9000 ft should be advised to acclimization at 8000 to 9000 ft for a few days before moving to higher altitudes. For higher altitudes, travelers should move sleeping altitude no higher than 500 m (1600 ft) per day and to plan on spending an extra day for acclimatization for every 1000 m (3300 ft), if possible. For abrupt ascent, pediatric travelers may require acetazolamide, prescribed as 2.5 mg/kg/dose every 12 hours, up to the standard adult dose of 125 mg twice per day. Travelers should begin acetazolamide 1 day before ascent and continue for the first 2 days at altitude. Dexamethasone is generally reserved for treatment of altitude illness.[53]

THE PEDIATRIC TRAVELER'S HEALTH KIT

Children traveling to developing countries may have unique exposures, particularly if they are traveling to remote locations or will have close contact with other children. Depending on the travel itinerary, children may need prescriptions for malaria chemoprophylaxis, antibiotic for self-treatment of travelers' diarrhea, and medication to prevent high-altitude sickness. Consideration should be given to inclusion of the following medications as part of the traveler's health kit: rectal preparations (suppositories) of selected medications, such as acetaminophen; topical treatments for lice and scabies for pediatric travelers to developing countries who may have extensive contact with local children; and a topical antibiotic, such as mupirocin, for bacterial skin infections.[53,100] Children with history of anaphylaxis or serious allergic reactions should have a sufficient number of epinephrine pens and antihistamines in tablet or liquid form. Any medications purchased abroad should be obtained from a reliable pharmacy because of concern about counterfeit drugs, especially in developing countries. Adults accompanying these children and teenagers should consider obtaining basic first aid and safety training before departure. Although air travel is safe for healthy newborns, infants, and children, a few issues should be considered in preparation for travel. Children with chronic heart or lung problems may be at risk for hypoxia during flight, and a physician should be consulted before travel. Insurance coverage for illnesses and accidents while abroad should be verified before departure.[65] Consideration should be given to purchasing special travel insurance for airlifting or air ambulance to an area with adequate medical care.[53]

INTERNATIONAL TRAVEL INFORMATION RESOURCES

One of the most important functions a clinician can fulfill in preparing a pediatric patient and parents for international travel is to provide up-to-date and accurate travel health information and recommendations for preventing illness. Many varied sources of information are available, including software packages and databases designed specifically for use in travel medicine and pretravel care.[73,94] Increasingly, the Internet and computer-based travel resources are being used by practitioners and consumers alike because they provide current information to appropriately and effectively counsel and treat international travelers. Two reviews have provided comprehensive summaries of travel medicine resources.[73,94] Table 231-4 is a summary of selected travel health resources that can be useful for providing health care professionals and parents with essential information on health risks in specific travel destinations (including endemic or epidemic diseases) and current travel health recommendations (including immunizations and chemoprophylaxis). Travelers also should be aware of the need for health insurance and emergency evacuation coverage during travel and medical assistance in the event of a travel-related illness; a variety of companies offer these services, and travelers should investigate options before making any purchases. This summary is not meant to be comprehensive; because resources are constantly changing, clinicians are advised to review and to compare sites for availability and updated information and recommendations.

CHAPTER 232

Infectious Disease Considerations in International Adoptees and Refugees

Mary Allen Staat

Each year thousands of children immigrate to the United States to begin a new life (Fig. 232-1). The focus of this chapter will be on two groups of immigrants—refugees and internationally adopted children. Refugees are noncitizen immigrants who are unable or unwilling to return to their country of origin because of persecution or fear of persecution.[79] Internationally adopted children are immigrants that are classified as orphans; however, most of these children are not truly orphaned, but have been abandoned by or separated from both parents.[79] These children generally will be given U.S. citizenship as they arrive or shortly after they arrive in the United States to join their new families.

In 2010, a total of 73,293 refugees arrived in the United States.[79] Nearly 85 percent of these refugees came from just six countries: Iraq (25%), Burma (23%), Bhutan (17%), Somalia (7%), Cuba (7%), and Iran (5%). Although these are the most prevalent countries, refugees have come to the United States from countries all around the world, with the exception of northern Europe, Australia, New Zealand, and Canada. Of refugees immigrating to the United States in 2010, 36 percent were younger than 20 years of age and 48 percent were females. The ages of the children were fairly evenly distributed—younger than 5 years (26%), 5 to 9 years (26%), 10 to 14 years (24%), and 15 to 19 years (23%). Only 1 percent of refugee children were younger than 1 year of age.

Over the past 20 years, international adoption has been a popular way to build families.[80] Since 1999, more than 200,000 children have been internationally adopted to families in the United States. The peak of international adoptions was in 2004, with 22,990 children immigrating to the United States; 83 percent of children came from just five countries: China (31%), Russia (26%), Guatemala (14%), South Korea (8%), and Kazakhstan (4%).[80] However, since 2004, a dramatic decline has occurred in the number of adoptions and the countries where children are adopted from is far more diverse. In 2010, only 11,100 children were adopted internationally, with 83 percent of children coming from nine countries: China (30%), Ethiopia (23%), Russia (10%), South Korea (8%), the Ukraine (4%), Taiwan (3%), India (2%), Colombia (2%), and the Philippines (2%).[79] Several countries that once allowed adoption, such as Romania, Vietnam, Cambodia, and Guatemala, are now closed to adoptions or have dramatically decreased the number of international adoptions from their countries. For example, in 2008, the largest numbers of adopted children were from Guatemala, with 4123 adoptions. In contrast, after the United States stopped processing Guatemalan adoptions in 2010, only 49 children were adopted from Guatemala.[80] In addition, a change has been seen in the medical needs of internationally adopted children. Over the past few years, China has shifted to primarily referring children with special needs such as congenital heart disease, cleft lip and palate, limb deficiencies, anorectal malformations, and spina bifida. In previous years, the majority of children referred to families from China were healthy infants without known medical conditions.

In contrast to refugee children, internationally adopted children are more likely to be girls (56%), largely because of increased availability of girls from China, and are more likely to be younger, with 73 percent of children younger than 5 years of age and 21 percent younger than 1 year of age at the time of adoption.[79] However, the age and gender of adoptees also has changed over time. In 2004, 65 percent of adopted children were girls and 41 percent were younger than 1 year of age and 86 percent were younger than 5 years of age.[80] With the arrival of older children, health care providers need to be aware that they will have an increased risk for malnutrition, infectious disease exposures, and unmet medical needs, as well as a more difficult transition to joining their family in contrast to younger adoptees in the past.

Children available for international adoption generally have resided all or most of their lives in orphanages before coming to the United States. The exception is South Korea, where nearly all children are placed in foster care until their adoption. In more recent years, some children from China have also been placed with foster families until adopted.

Because refugees and internationally adopted children come from resource-poor countries, physicians and other health care providers need to be aware of the global prevalence of infectious diseases that are seen less commonly in native-born North Americans. Both refugees and internationally adopted children are at increased risk for common infectious diseases such as tuberculosis (TB), intestinal parasites, dermatologic infections, and infestations. In addition, in countries where resources are few

FIGURE 232-1 ■ A group of internationally adopted children. (See companion Expert Consult website for color version.)

and infrastructure limited for screening and prevention programs for hepatitis B, hepatitis C, human immunodeficiency virus (HIV), and syphilis, the prevalence is higher in contrast to the prevalence in the United States.

Although many similarities exist in the infectious disease considerations for refugees and internationally adopted children, several important differences also are found. Refugee and internationally adopted children differ in terms of the general medical screening they receive before their arrival to the United States.[4,8,14-16] Most refugees undergo organized screening evaluations before emigration visas are issued. Children have predeparture screening and a physical examination, and, depending on their country of departure, they may receive predeparture treatment for malaria, intestinal parasites, or tissue parasites. In contrast, only adoptees from certain countries with high rates of TB, such as China and Ethiopia, have been required to undergo this organized screening procedure for TB. Second, because medical screening for refugees is usually sponsored by responsible medical organizations, results of testing are typically accurate. In internationally adopted children, medical testing may be incomplete and is typically done shortly after birth or on entrance to the orphanage. However, families should expect to receive results for HIV, syphilis, and hepatitis B surface antigen testing with their referral information. For some countries, such as Ethiopia, HIV polymerase chain reaction (PCR) and hepatitis C test results also are provided. For Russian referrals, hepatitis C testing is often done as well. Although the reliability of testing done in the child's birth county has been a concern in the past, in recent years the testing has generally proven to be accurate when repeated in the United States. Third, preventive measures such as immunizations, vitamin supplementation, and dental care are provided for most refugee children while still in refugee camps; in adoptees, no standard approach is followed in the provision of these measures from country to country or even within a given country. Differences also exist in the types of infectious diseases and risks for acquiring these diseases in refugee children in contrast to internationally adopted children. Although both groups are susceptible to a variety of infectious agents, because the countries of origin and the living conditions differ, refugee children are more likely to have been exposed to infections such as typhoid fever, malaria, filariasis, flukes, and schistosomiasis, which are uncommonly seen in internationally adopted children from countries outside of Africa.

Health care professionals will inevitably have the opportunity to provide care for these children as they immigrate to the United States and should therefore be knowledgeable of the infectious disease issues they may encounter and the need for screening for infectious diseases in these populations.

OVERALL EVALUATION

Because of the predominance of infectious diseases in resource-poor countries, recommendations for screening tests in refugees and internationally adopted children have been weighted toward infectious disease processes and this will be the focus of this chapter. It is important, however, that the initial assessment include all aspects of general health, including evaluation of growth and development and vision, hearing, and dental evaluations.[6,8,14,15,84] For internationally adopted children, several others tests are recommended, including testing for blood lead concentration, complete blood cell count with red blood cell indices, and differential of white blood cells to evaluate for eosinophilia, glucose-6-phosphate dehydrogenase screening, hemoglobin electrophoresis, measurement of thyroid-stimulating hormone concentration, and examination for congenital anomalies (including fetal alcohol syndrome).[4] Similar to adoptees, a complete blood count and a lead level is recommended for refugees.[15] Additional tests, such as a urinalysis to determine if there is hematuria (for schistosomiasis) and screening for sexually transmitted infections are recommended. Mental health screening is encouraged if services are available.

Although many immigrant children may appear healthy on arrival, children should be evaluated by a health care professional within 2 weeks after arrival to ensure that their initial health care needs are addressed, initial screening is done and a plan for receiving preventive services such as immunizations are initiated. Table 232-1 outlines the infectious disease screening tests recommended for refugee and internationally adopted children with details for each condition outlined in the following discussion.

INFECTIOUS DISEASE SCREENING

Viral Hepatitis

Hepatitis A

Virtually all people residing in resource-poor countries have contracted hepatitis A by early adulthood and have hepatitis A immunoglobulin (Ig)G antibodies.[26] The prevalence of past hepatitis A infection varies by country and age. In a study examining the prevalence of acute and past hepatitis A infection in internationally adopted

TABLE 232-1 **Infectious Disease Screening for Refugee and Internationally Adopted Children**

Condition or Test	Refugee Children	Internationally Adopted Children
Hepatitis A Virus (Acute Infection)		
Hepatitis A IgM antibody	Not recommended	All
Hepatitis B Virus		
Hepatitis B surface antigen (HBsAg)	All	All*
Hepatitis B surface antibody (anti-HBs)	All	All*
Hepatitis B core antibody (anti-HBc)	All	All*
Hepatitis C Virus		
Hepatitis C antibody	Some	All*
Syphilis		
Nontreponemal test (RPR, VDRL, or ART)	≥15 years of age	All
Treponemal test (TPPA, MHA-TP, or FTA-ABS)	Not recommended	All
Human Immunodeficiency Virus		
Human immunodeficiency virus 1 and 2 antibody	≥13 years of age	All*
Recommended	<13 years of age	
Encouraged		
Tuberculosis		
Tuberculin skin test (TST)	All	All*
or		
Interferon-γ release assay	≥5 years of age	≥5 years of age
Intestinal Parasites		
Microscopic evaluation of stool for ova and parasites	All (2 specimens)†	All (3 specimens)
Giardia intestinalis and *Cryptosporidium* antigen	All (1 specimen)†	All (1 specimen)
Bacterial Enteric Infection		
In children with diarrhea-bacterial stool culture	All	All
Chagas (Endemic Areas)		
Trypanosoma cruzi serologic testing	All	All
Complete Blood Count	All	All
Eosinophilia with negative stool ova and parasite for helminths		
Strongyloides serologic testing	All	All
Schistosoma serologic testing (endemic countries)‡		
Lymphatic Filariasis (Endemic Areas)		
Filaria serology	All	≥2 years of age
Chagas (Endemic Areas)		
Trypanosoma cruzi serologic testing	All	All
Malaria Screening (Endemic Areas)		
Malaria polymerase chain reaction	All without pretreatment	Not recommended
Hematuria (Schistosomiasis)		
Urinalysis	All	Not recommended

*Consider reassessing 6 mo after arrival.
†All should be screened if there was no presumptive treatment before arrival to the United States; see guidelines for evaluation for intestinal parasites in refugees with presumptive treatment (http://cdc.gov/immigrantrefugeehealth/guidelines/domestic/intestinal-parasites-domestic.html).
‡Some experts recommend serologic testing regardless of whether eosinophilia is present.
ART, Automated reagin test; *FTA-ABS,* fluorescent treponemal antibody absorption; *MHA-TP,* microhemagglutination–*Treponema pallidum; RPR,* rapid plasma reagin; *TPPA, Treponema pallidum* particle agglutination; *VDRL,* Venereal Disease Research Laboratory.

children, 1 percent of children had acute hepatitis A infection (positive hepatitis A IgM) on arrival the United States and 29 percent had evidence of prior infection (positive total hepatitis A antibody).[1] In this study, the prevalence of prior infection increased with age; 13 percent of children younger than 2 years of age were immune in contrast to 80 percent of children 12 to 17 years of age. The highest region-specific prevalence was in Africa (72%), and the lowest was in the Asia and Pacific Rim Region (17%).

Given the high prevalence of hepatitis A virus (HAV) in these countries, there is an ongoing risk for infection of children while in their country of origin. In internationally adopted children, children may be incubating HAV infection at the time of adoption and could transmit the virus to their adoptive families and others while in country or after arrival to the United States. Several cases have been reported of HAV transmitted from internationally adopted children to family members and close contacts.[1,34,76,85] Therefore, adoptive parents and any accompanying family members should be immunized against hepatitis A or have documented immunity to HAV infection before international travel to receive their child.[7,25] It is also recommended that hepatitis A vaccine be administered before the arrival of the adoptee to all susceptible nontraveling people who plan to have close contact with an internationally adopted child from a country with high or intermediate hepatitis A endemicity.

In the United States, hepatitis A vaccine is recommended for all children 12 months of age and older.[23,28] Hepatitis A vaccine is not routinely administered to children or adults in resource-poor countries. Because the prevalence of past HAV infection is high in these countries, antibody testing can be done to determine HAV immunity. Hepatitis A antibody testing (total or IgG) should be considered in children older than 1 year of age for both refugees and internationally adopted children to determine the need for this vaccine.[3,4,15]

Infection with hepatitis A is often difficult to diagnose clinically in children; as many as 90 percent of children younger than 6 years of age and 50 to 60 percent of older children are anicteric.[23,26] Thus, most young children will not have signs or symptoms of hepatitis A, yet those who are infected may shed the virus for months. To identify hepatitis A infection in asymptomatic children, hepatitis A IgM antibody testing should be done.[4] When acute infection is found in a child, secondary cases can be prevented by providing hepatitis A vaccine to unvaccinated family members and close contacts of the case.[7,23,25] Although most children are asymptomatic, viral hepatitis should be considered in children with symptoms such as vomiting and loss of appetite, when accompanied by fever and an enlarged, tender liver even in the absence of jaundice.[4,23,26]

Hepatitis B

Routine screening for hepatitis B virus (HBV) infection is recommended for all refugees and internationally adopted children.[4,8,14,15] Most children who have hepatitis B infection and are carriers are asymptomatic. Therefore, screening is important to identify these children so appropriate management can be initiated and unvaccinated household contacts and caregivers can be vaccinated or be given hepatitis B Ig if they have had a significant exposure to blood of a hepatitis B carrier. The prevalence of hepatitis B infection is higher in resource-poor countries than in the United States. In Asia, Africa, and Central and South America, the prevalence of hepatitis B ranges from 2 to 7 percent in contrast to only 0.5 percent in the United States.[27] Several studies have shown rates of infection in refugee[12,17,49,53] and internationally adopted children* mirror the reported rates in their country of origin. Immigrant children have typically acquired HBV by vertical transmission, although bloodborne infection and horizontal transmission also have been implicated. In international adoptees, the highest reported rates were in Romanian adoptees from the early 1990s, with 53 percent having evidence of past or present infection and 20 percent with active infection.[39,45,46,62,64] More recent studies have consistently shown a lower range of prevalence (1% to 5%).† Several reasons explain the high prevalence of hepatitis B infection in Romanian adoptees. During that period, Romania had an overall high prevalence of hepatitis B and therefore many children in orphanages were infected with hepatitis B. Needles were commonly reused for immunizations and other injections. Transmission was facilitated through contaminated needles and close contact with children infected with hepatitis B. Hepatitis B vaccine was not used during that period. In addition, hepatitis B screening was not routinely done in children available for adoption; thus, many children arrived to the United States with unsuspected hepatitis B. In more recent years, hepatitis B vaccine in infants and screening for hepatitis B infection is routinely done and reported in the referral information. Thus, the diagnosis of hepatitis B infection is nearly always known before adoption and this condition is considered to be a special need.

Hepatitis B screening tests, including the hepatitis B surface antigen (HBsAg) and antibodies to surface (anti-HBs) and core (anti-HBc) antigens, are recommended in the medical evaluation of both internationally adopted children and refugees.[4,8,14,15] All three tests should be done to determine whether the child is immune as a result of immunization (anti-HBs positive only), has recovered from infection (anti-HBs and anti-HBc positive), or has acute or chronic hepatitis B (HBsAg and anti-HBc positive). Patterns of hepatitis B serology can be found in Chapter 156. In a child found to be HBsAg-positive, repeat testing should be done 6 months later. If the HBsAg persists for longer than 6 months, the child has chronic hepatitis B infection. If the child no longer has HBsAg and has developed anti-HBs, the child had acute infection and has recovered and is no longer able to transmit the virus to others. Children with acute or chronic hepatitis B (positive HBsAg) can transmit hepatitis B to others. A positive hepatitis B IgM differentiates acute hepatitis B from chronic hepatitis B. Children with acute or chronic hepatitis B should have additional testing

*References 2, 42, 43, 54, 58-60, 65, 73.
†References 2, 42, 43, 54, 56, 58, 60, 65, 73.

done, including testing for HBeAg, HBeAb, and serum hepatic enzyme levels. HBsAg-positive children should be followed closely by a hepatologist for management. Hepatitis D virus (HDV), which is seen only in patients with hepatitis B infection, occurs in North Africa, parts of South America, and the Mediterranean Basin.[4] Testing for HDV is not widely available, but is recommended in patients from these regions who are found to have hepatitis B infection; however, a positive test does not change clinical management. For children who initially test negative for HBsAg, HBsAb, and HBcAb, some experts recommend repeat testing for hepatitis B approximately 6 months after arrival to ensure the child was not infected just before arrival to the United States.[4] Children with acute or chronic hepatitis B should have serologic testing for hepatitis A to determine the need immunization with hepatitis A vaccine and for hepatitis C for overall management and treatment considerations.

Ideally, the family members of internationally adopted children should be vaccinated against hepatitis B before the child joins the family. If this has not been done, the household contacts of children with acute or chronic hepatitis B (HBsAg-positive) must be vaccinated promptly. Hepatitis B is easily transmitted to unvaccinated household contacts. Up to 20 percent of household contacts will become HBsAg-positive with 5 or more years of exposure within the home,[27,39] and transmission of hepatitis B from newly adopted children to their parents has been documented.[36,39,70]

Hepatitis C

Screening for hepatitis C is recommended for all internationally adopted children because of high rates of hepatitis C in the countries of origin of adoptees and because of the difficulty in determining risk factors for these children.[4] In refugees, testing is recommended if there is a history of specific risk factors such as current or former injection drug use, receipt of blood products, or residence in settings with a documented high prevalence of hepatitis C.[14,15] Data on the prevalence of hepatitis C in both refugee and internationally adopted children are limited. One study examining the prevalence of hepatitis C antibody in internationally adopted children found the prevalence to be less than 1 percent.[65] Antibody testing with an enzyme immunoassay (EIA) should be done with the initial screening. If the antibody is positive, PCR should be done to confirm infection. Maternal antibody may be present until a child is 18 months of age. Children found to have hepatitis C infection should be immunized for hepatitis A and B and should be referred to a hepatologist for further management (see Chapter 176).

Human Immunodeficiency Virus 1 and 2 Infections

In the past, as part of the required overseas medical assessment, HIV testing was required for all immigrants and refugees 15 years of age and older.[14] Children younger than 15 years of age were tested for HIV if history or examination raised concern about possible HIV infection (e.g., maternal history of HIV infection or history of rape or sexual assault). Since January 2010, HIV testing is no longer required for immigration medical assessment. The exception is that HIV testing still is recommended for people diagnosed with active TB. For refugees, HIV testing is recommended after arrival in the United States for persons 13 through 64 years of age and encouraged for those younger than 13 years of age (http://www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/screening-hiv-infection-domestic.html).

The decision to screen children younger than 13 years of age depends on history and risk factors (e.g., receipt of blood products and maternal drug use), physical examination findings, and prevalence of HIV infection in the child's country of origin. If there is a suspicion of HIV infection, testing should be performed before administration of live vaccines.

In contrast, most internationally adopted children have been tested for antibodies to HIV-1 by enzyme immunoassay (EIA) in their birth country. In Ethiopia, an HIV-1 PCR test is also done. In children born to mothers with HIV and found to have antibodies to HIV in their country of origin, HIV-1 PCR testing is generally done. In more recent years, children known to be exposed to HIV have been given antiretroviral drugs. For internationally adopted children, on arrival to the United States, routine screening by EIA is recommended.[4]

Reports of HIV infection in internationally adopted children are rare. In the early 1990s, two cases of Romanian adoptees with HIV infection were reported.[44] Subsequently, Romania was found to have high rates of HIV in institutionalized children that were not felt to be maternally transimitted.[38] The high prevalence was found to be associated with transmission through contaminated needles and blood products. In a more recent case series, there have been no reports of HIV infection in adoptees.[65] In contrast to past years when children infected with HIV were not permitted to be adopted internationally, these children may now be adopted by families in the United States. Many children with HIV infection have joined their new families through adoption and they have generally been treated with antiretrovirals before arrival.

For internationally adopted children, HIV testing with an enzyme-linked immunosorbent assay (ELISA) is recommended shortly after their arrival. Positive or indeterminate results should be resolved with use of HIV DNA PCR to detect HIV-1 virus (see Chapter 191). If antibody testing by EIA is negative and clinical suspicion exists for HIV infection, HIV DNA PCR testing should be done. Retesting children older than 6 months of age after arrival to the United States should be considered.[4] Clinicians should be prepared to provide care and resources for children arriving to the United States with HIV infection.

Preadoptive testing for HIV-2 infection is not performed routinely. HIV-2 infection is prevalent in some African nations and is now recognized on several other continents; perinatal transmission appears to be limited. Symptoms suggestive of HIV infection with negative ELISA results for HIV-1 should prompt testing for HIV-2.[4]

Bacterial Infections

Syphilis

Refugees and internationally adopted children 15 years of age and older are routinely screened for syphilis before coming to the United States.[15] Immigrants with positive results are required to complete treatment before arriving to the United States. Screening of all refugees 15 years of age and older is recommended regardless of the overseas results.[14,15] Children who are younger than 15 years of age should be screened if there is a history of sexual activity or sexual assault or a history of maternal syphilis. In addition, all refugees immigrating from a country endemic for other treponemal infections such as yaws, bejel, or pinta should also be screened. Refugees of any age should be tested if there is clinical suspicion for syphilis.

Most internationally adopted children will have documentation of syphilis screening done in their birth country. For children with a history of syphilis or syphilis exposure, it is difficult to determine when the birth mother contracted syphilis and if she was treated and followed appropriately. In addition, in children with suspected syphilis exposure, details of the evaluation and prescribed treatment regimens are often incomplete or uninterpretable. Even though syphilis has rarely been reported in adoptees,* all internationally adopted children should be screened on arrival with both a nontreponemal test (rapid plasma reagin, Venereal Disease Research Laboratory, automated reagin test) and a treponemal test (microhemagglutination–*Treponema pallidum*, fluorescent treponemal antibody absorption, or *T. pallidum* particle agglutination) (see Chapter 143).[4] A positive treponemal test result warrants a complete and thorough evaluation to document the extent of the disease and to ensure adequate treatment regardless of a report of prior treatment. Because a positive treponemal test may be seen in pinta, bejel, yaws, and syphilis, it is important to consult with a specialist with expertise in these infections if the child is from a country where other treponemal infections are endemic.

Tuberculosis

TB is highly prevalent in the countries of origin for both refugees and internationally adopted children. Therefore, screening on arrival to the United States is recommended for both groups.[4,8,14,15] In 2010, 60.5 percent of all TB cases in the United States were among foreign-born people.[30] The rate of TB in foreign-born persons in the United States is 18.1/100,000; in U.S.-born persons, the rate is 1.6/100,000. In addition, in the United States in 2009, the majority (89.4%) of multidrug-resistant TB cases were in foreign-born persons. In children, 22 percent of TB cases were foreign-born. Case rates were significantly higher in foreign-born children (12.2/100,000) than in children born in the United States (1.1/100,000).[61]

Both refugees and internationally adopted children are at increased risk for TB infection. In immigrants and refugees, a high prevalence of latent tuberculosis infection (LTBI) was found in studies conducted in Minnesota (49%),[49] San Francisco (40%),[32] Buffalo (20%),[53] and Maine (35%).[37] A study in San Diego County found that 7 percent of immigrants screened had active pulmonary TB and 76 percent had LTBI.[50]

Overall, LTBI in internationally adopted children* appears to be lower than that seen in refugees.† This is likely due to the younger age and lower risk of living conditions of in this group of children. However, with the increased numbers of children coming from Ethiopia, a country with higher rates of tuberculosis, the rate of LTBI and tuberculosis in internationally adopted children is likely to increase. In two large studies in which all tuberculin skin tests (TSTs) were evaluated by a health care professional, 14 to 21 percent of international adoptees had LTBI.[52,78] The highest proportion with LTBI was seen in children from Russia and Eastern Europe (29%), and the lowest was in children adopted from China (10%). Of note, very few children from Africa were included in these studies. Children with initially negative TSTs had their TSTs repeated at least 3 months later, and 13 to 20 percent of the TSTs were positive, suggesting a high proportion of children initially had false positive TSTs. The authors postulate that this could be due to anergy, testing too soon after infection, or boosting from TB infection or BCG.

TB disease in international adoptees has rarely been reported.[31,46] In the first series of Korean adoptees, the overall prevalence was less than 1 percent, but two children had active TB and both had nonreactive TSTs.[46] One child had pneumonia caused by *Mycobacterium tuberculosis* and recovered. The other child had TB meningitis and died. These cases illustrate the importance of considering TB in the differential diagnosis even in children with negative TSTs. In the second case report,[31] a child with TB adopted from the Marshall Islands infected his female guardian and 20 percent of the contacts identified. On arrival in the United States, he had a TST done but the test was never read. He had cavitary TB but it was not diagnosed until his guardian developed TB.

In the past, refugees older than 15 years of age and children younger than 15 years with concern about TB exposure or disease were screened with a chest radiograph before arriving in the United States. If the chest radiograph was abnormal, microscopic evaluation of sputum or gastric aspirate for acid-fast bacilli is performed. Refugees who were sputum-positive are banned from entry until sputum smears are negative. In 2007, a major revision of the overseas TB screening requirements for immigrants and refugees bound for the United States was implemented that required TB screening for all people.[14] Information about the screening and implementation is available at the CDC's website (http://www.cdc.gov/ncidod/dq/panel_2007.htm). International adoptees from certain countries with high rates of TB (China and Ethiopia) now fall under the same

requirements as other immigrants and refugees. For other adoptees, screening in the country of origin appears to be inconsistently done and generally is documented only in older children.

For both refugees and internationally adopted children, screening for TB should be done shortly after arrival to the United States.[4,8,14,15] This can be done at the initial assessment by placement of a TST (5 tuberculin units purified protein derivative) (Fig. 232-2). The test should be read 48 to 72 hours later by a health care professional. A reading of 10 mm or greater of induration is considered positive for both refugees and internationally adopted children arriving from a country endemic for TB. A reading of 5 mm or more is considered positive if there is a known contact with a person with active TB, an abnormal chest radiograph finding, signs or symptoms suggestive of TB, or evidence of immunosuppression. Children with a positive TST should have a thorough physical examination and chest radiograph performed to assess for *M. tuberculosis* disease. If the chest radiograph and physical examination are normal and the skin test is 10 mm or greater of induration, the diagnosis of LTBI is made and treatment with a 9-month course of isoniazid is begun. Similarly, a child with 5 to 9 mm of induration who has known exposure to someone with active TB or who is receiving immunosuppressive therapy or has an immunosuppressive condition, including HIV, with no evidence of disease, should receive isoniazid therapy as well. Retesting of TST-negative children 6 months or longer after arrival should be considered for all children given the high rate of false-negative TSTs shortly after arrival to the United States.[4,52,78]

Interferon-γ release assays (IGRAs), such as QuantiFERON Gold and T-SPOT.TB are available but are not currently recommended for children younger than 5 years of age, because of the lack of published data for younger children.[5] These assays use antigens that are secreted by *M. tuberculosis*–complex organisms but not by the Calmette-Guérin bacillus from the BCG vaccine. For TB disease, their sensitivity is comparable to that of the TST in children 5 years of age or older. For TB infection, the specificity of these tests is higher in contrast to that of TSTs but the sensitivity is not known. Logistical issues exist with the use of these tests because the test relies on stimulation of live blood mononuclear leukocytes with antigen, in vitro. In addition, these tests are more expensive than TSTs. For immunocompetent children 5 years of age and older, IGRAs can be used in place of a TST to confirm cases of TB or cases of LTBI. Similar to a positive TST, a child with a positive result from an IGRA should be considered infected with *M. tuberculosis* complex; however, a negative result from an IGRA cannot definitively rule out TB infection.

Although most refugees and internationally adopted children with *M. tuberculosis* infection have LTBI, disease should be considered in children with pneumonia or nonspecific symptoms such as fever, malaise, growth delay, weight loss, cough, night sweats, and chills. In children, pulmonary TB is the most common site of infection, accounting for 77 percent of cases, followed by lymphatic TB in 16 percent of children.[61] Chest radiographs may reveal adenopathy, segmental or lobar infiltrates, or pleural effusion. Cavitary lesions and miliary disease are less commonly seen. Extrapulmonary manifestations of the central nervous system, middle ear and mastoids, lymph nodes, bone, joints, and skin also can be seen. Every effort should be made to recover the organism in children with suspected disease to determine the susceptibilities of the organism. Many children arrive from countries in which drug-resistant *M. tuberculosis* is common. Gastric aspirates, bronchoscopy, or both, can be useful adjuncts in a child too young or too ill to expectorate sputum.

Initial management of active TB disease in refugees or internationally adopted children should include isoniazid, rifampin, pyrazinamide, and at least one other agent to ensure bactericidal coverage while culture results and susceptibility testing are pending (see Chapter 96).[5] The most recent resistant patterns from the child's country of origin should be considered along with any other epidemiologic information that can be obtained when making treatment decisions, especially if the cultures are negative.

Vaccination with BCG is common in most resource-poor countries. A history or evidence of BCG vaccine receipt is not a contraindication to the placement of a TST.[4,5] Studies have demonstrated that placement of a TST after BCG vaccination fails to elicit induration of 10 mm or greater.[48,67] Thus, the history of BCG vaccine should not affect the interpretation of purified protein derivative.

BCG vaccination can be recognized by a 2- to 4-mm scarification, often seen on the left deltoid. Documentation of vaccination should be made in the child's vaccine record, and the scar, if present, should be documented on the physical examination record. Occasionally, complications from BCG vaccination can occur. These may include enlargement of regional lymph nodes or a nodule or ulcer that may or may not be draining at the vaccination site (see Fig. 232-3). The lesion is granulomatous; culture of the lesion will yield *Mycobacterium bovis*. No consensus exists regarding the management of this condition. The outcome of these lesions varies. Some lesions resolve without treatment. Other lesions have been excised for diagnostic reasons, and others have been

BCG granuloma

FIGURE 232-3 ■ Internationally adopted child from Vietnam with a BCG granuloma on shoulder. (See companion Expert Consult website for color version.)

reported to require excision. Medical treatment with isoniazid, erythromycin, or clarithromycin has been used with success.[35,77]

Enteric Bacterial Infections

In contrast to intestinal parasites, bacterial enteric pathogens appear to be less common in immigrants and adoptees; however, most studies have not assessed systematically for bacterial causes. Children with bloody diarrhea or diarrhea associated with high fever should have stool examined for bacterial enteropathogens (e.g., *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter)* as part of the initial evaluation. Some experts also recommend obtaining stool cultures in newly arrived adoptees who have diarrhea.[4] However, if a bacterial pathogen is identified, treatment may not be indicated or needed if symptoms have resolved.

Intestinal Parasites

Intestinal parasites are common in both refugee* and internationally adopted† children (Table 232-2). Rates of infection vary by age and country of origin. Most children typically have not had testing before coming to the United States. However, presumptive treatment of refugees from certain regions before departure to the United States has been recommended since 1999, and screening strategies for these two groups are different.[16,75] Specifically, all refugees from the Middle East and South and Southeast Asia are recommended to receive a single dose of albendazole for round worms and ivermectin for *Strongyloides*. African refugees also should receive presumptive treatment for *Strongyloides*, and for those originating from areas endemic for schistosomiasis, presumptive treatment with praziquantel should be given. In African countries where Loa Loa is endemic, ivermectin should not be given for *Strongyloides* because treatment with this drug in the presence of Loa Loa has been associated with encephalopathy. Therefore in Loa Loa–endemic areas, 7 days of albendazole should be given. Additional details of the country-specific recommendations, timing, dosing, and duration of treatment can be found in the CDC's guidelines for refugee and immigrant care.[16]

In internationally adopted children, the reported prevalence of intestinal parasites has varied from 9 to 51 percent, depending on the age of the child and country of origin.* Older children and children originating from countries other than Korea have been found to be at

TABLE 232-2 **Pathogenic and Nonpathogenic Intestinal Parasites**

Parasite Type	Pathogens	Nonpathogens
Protozoa	*Giardia intestinalis*	*Endolimax nana*

	Microsporidium spp.	*Retortamonas intestinalis*
		Trichomonas hominis
		Trichomonas tenax
Helminths		
Nematodes	*Ascaris lumbricoides* (roundworm)	
	Trichuris trichiura (whipworm)	
	Strongyloides stercoralis (threadworm)	
	Enterobius vermicularis (pinworm)	
	Necator americanus (hookworm)	
	Ancyclostoma duodenale (hookworm)	
Cestodes	*Hymenolepsis* spp.	
	Taenia saginata (beef tapeworm)	
	Taenia solium (pork tapeworm)	
	Schistosoma spp.	

*Controversy exists regarding the pathogenicity of this organism.

*References 9, 10, 12, 47, 49, 66, 75, 84.
†References 2, 43, 45, 54, 56, 58, 60, 65, 72.

*References 2, 43, 45, 54, 56, 58, 60, 65, 72.

highest risk for intestinal parasites. *Giardia intestinalis* has been the most commonly identified pathogen in all studies, with as many as 19 percent of children infected. Helminthic infections have been less frequently identified (<3%), with *Hymenolepsis* spp., *Ascaris lumbricoides*, and *Trichuris trichiura* most often reported. In the largest study, the overall prevalence of intestinal parasites in internationally adopted children was 29 percent.[72] In this study, the prevalence of intestinal parasites was similar in children with and without gastrointestinal symptoms and no significant difference was seen in malnourished children in contrast to children who were not malnourished.

Several studies report the prevalence of intestinal parasites in refugees, but few give pathogenic-specific data by age and country. In a large study of 26,956 refugees from Southeast Asia and Africa, the prevalence of intestinal parasites was examined.[75] The median age was 19 years, and 30 percent were children 2 to 14 years of age. For African refugees who were not pretreated, 7 percent had *Giardia* and 24 percent had at least one nematode, with *Trichuris* being most commonly identified. For Southeast Asian refugees, 12 percent had *Giardia* and 19 percent had at least one nematode, but hookworms were the most prevalent, at 11 percent. Children 2 to 14 years of age were significantly more likely than adults to have *Ascaris*, *Trichuris*, and *Giardia*, while hookworms were found more often in adults. In contrast, in another study, 17 percent of refugee children were found to have *Giardia* and 19 percent had helminthes, with hookworms most commonly seen.[9] This study found a high rate of hookworm in Bosnian refugees and found different rates of overall and pathogenic specific recovery by region. Interestingly, this study found that refugees who reported gastrointestinal symptoms were significantly less often infected in contrast to those without symptoms ($p < .001$).

Both refugees and adoptees should be screened for intestinal parasites on arrival to the United States.[4,8,14-16] The diagnosis for most intestinal parasites is done by examination of stool preserved in formalin and polyvinyl alcohol or sodium-acetate formalin for ova and parasite testing. Testing multiple stool specimens increases the sensitivity of microscopic examination for ova and parasites.[11,40,72] In one study in internationally adopted children, the sensitivity was 79 percent using one specimen and 92 percent for two specimens and a third specimen identified parasites in an additional 8 percent of children.[72] Examination by an experienced technologist is critical in identifying intestinal parasites. One stool specimen should also be evaluated for *G. intestinalis* and *Cryptosporidium parvum* using antigen testing.[4] Repeat stool samples are essential to assess the effectiveness of treatment for the identified parasite or determine the presence of new (or newly found) pathogens. If the child remains persistently symptomatic, additional stool sample examinations are warranted and testing for other parasites such as *Cyclospora* and *Strongyloides stercoralis* should be considered.

Tissue Parasites

In refugees or internationally adopted children who have negative stool ova and parasite examinations and in whom eosinophilia (absolute eosinophil count exceeding 450 cells/mm^3) is found on complete blood count, additional serologic testing should be done.[4,8,14-16,69] Serologic testing for *S. stercoralis* should be performed on all children with eosinophilia and no identified pathogen commonly associated with an increased eosinophil count, regardless of country of origin. Serologic testing for *Schistosoma* spp. should be performed in children with eosinophilia and no identified pathogen commonly associated with eosinophilia from Sub-Saharan Africa, Southeast Asia, or areas of Latin America where schistosomiasis is endemic.

Testing for filariasis should be done for children older than 2 years of age with eosinophilia who come from areas where filariasis is endemic.[4,14-16] Multiple parasites cause filariasis; therefore, if testing is positive, consultation with an infectious disease specialist with expertise in this disease should be done to ensure the correct treatment is given. Serologic testing for *Strongyloides*, *Schistosoma* spp., and filariasis is available through the CDC.

Chagas Disease (American Trypanosomiasis)

Chagas disease is endemic throughout much of Mexico, Central America, and South America (Chapter 221) and is caused by *Trypanosoma cruzi*. The risk for Chagas disease varies by region within countries with endemic infection. Although no studies have been done to assess the prevalence of Chagas disease in refugees or internationally adopted children, screening is warranted because treatment of infected children is highly effective in contrast to treatment in adults.[4,14-16] Children may become infected by vertical exposure or from vectors. Countries with endemic Chagas disease include Argentina, Belize, Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, French Guiana, Guatemala, Guyana, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Suriname, Uruguay, and Venezuela. Serologic testing should only be performed in children 12 months of age or older because of the potential presence of maternal antibody. Testing can be done through the CDC.

Malaria

For internationally adopted children, routine screening for malaria is not recommended.[4] In refugees who do not have a contraindication, predeparture presumptive antimalarial therapy with artesunate-combination therapy should be given to all sub-Saharan African refugees arriving from countries endemic for *Plasmodium falciparum*.[14,15] Refugees from these countries without presumptive treatment before departure, should have postarrival testing done using malaria PCR. If PCR is not available, traditional blood films or a rapid antigen test may be used, recognizing that these tests are much less sensitive, especially in persons who are asymptomatic. Alternatively, presumptive treatment can be provided instead of testing. Refugees from malaria-endemic regions outside sub-Saharan Africa do not require postarrival testing or treatment. However, any refugee or internationally adopted child from a malaria-endemic region with signs or symptoms of malaria should be thoroughly evaluated.

Other Testing

A complete blood count is recommended for refugees and internationally adopted children.[4,8,14,15] The hemoglobin and red blood cell indices may identify children with anemia, iron deficiency, hemoglobinopathies, or malaria. Low white blood cell counts and lymphopenia may indicate HIV infection or malnutrition. Eosinophilia is common among refugees and suggests parasitic infection.[8,14,69] The prevalence of eosinophilia has not been reported in internationally adopted children. For refugees, a urinalysis is recommended to assess for hematuria and pyuria.[8,14,15] Hematuria may indicate schistosomiasis, and pyuria may reflect a urinary tract infection or renal TB.

Elevated blood lead levels have been reported in internationally adopted children[18] and refugees,[22] and both groups should have a blood lead concentration as part of their initial evaluation.[4,14,15]

OTHER VACCINE PREVENTABLE DISEASES

In addition to hepatitis A and hepatitis B, other vaccine-preventable diseases have been transmitted or brought into the United States by immigrants. One case of pertussis in an internationally adopted child from Russia has been reported,[20] along with several cases of measles imported by refugees[29] and internationally adopted children.[19,21,24] Clinicians should be aware of the signs and symptoms of measles and do proper testing if measles is suspected.

Dermatologic Infections and Infestations

Lice, scabies, fungal infections, and molluscum contagiosum are common in both refugees and internationally adopted children. The prevalence of these conditions has not been well documented. The physical examination should include careful evaluation for these entities so that appropriate treatment is given.

IMMUNIZATION GUIDELINES

Making immunization recommendations can be challenging for clinicians providing care for immigrant children. Most refugees arrive in the United States without immunization records, and most international adoptees have some documentation of receipt of immunizations. Refugee and internationally adopted children have typically had the opportunity to have received BCG, diphtheria-tetanus-pertussis–containing vaccines, poliovirus vaccine, hepatitis B, and measles vaccines in their countries of origin. In internationally adopted children, there has been an increase in documentation of *Haemophilus influenzae* type b vaccine, especially for children from South Korea, Guatemala, India, and China. For measles vaccine, most children will have received and have documentation of a monovalent measles vaccine. Mumps and rubella vaccines in combination with measles vaccine as MMR have been documented for adoptees from South Korea and Guatemala or as monovalent vaccines in older children from Eastern Europe and Russia. Pneumococcal conjugate and varicella vaccines are not routinely given but have been documented in records for children from South Korea and Guatemala. Although children may have documentation of some vaccine-preventable diseases, a clinical diagnosis of measles, mumps, rubella, varicella, or hepatitis A from the child's country of origin should not be accepted as evidence of immunity.

The *Immigration and Nationality Act* (INA) of 1996 requires immigrant visa applicants to provide proof of vaccination with at least the first dose of vaccines recommended by the Advisory Committee on Immunization Practice (ACIP) before entry into the United States.[3,14,15] These regulations apply to most immigrant children entering the United States; however, internationally adopted children who are 10 years of age or younger may obtain an exemption from these requirements. Adoptive parents are required to sign a waiver indicating their intention to comply with the ACIP immunization requirements within 30 days after the child's arrival in the United States. Refugees are not required to meet immunization requirements of the INA at the time of initial entry into the United States, but they must show proof of immunization when they apply for permanent residency—typically 1 year after arrival. Information about immunization requirements for immigrants is available on the CDC's website (http://www.cdc.gov/ncezid/dgmq/).

People immunized in other countries, including refugees and internationally adopted children, should be immunized according to the United States' recommended schedule for healthy infants, children, and adolescents. Only written documentation should be accepted as evidence of previous immunization.* The written records may be considered valid if the vaccines, dates of administration, numbers of doses, intervals between doses, and age of the patient at the time of immunization are comparable to current U.S. or World Health Organization (WHO) schedules (http://apps.who.int/immunization_monitoring/en/globalsummary/countryprofileselect.cfm). Overall, most vaccines used around the world are produced with adequate quality-control standards and are generally considered reliable. Immunization is one of the most important measures used to prevent diseases in resource-poor countries, and immunization of children is a priority worldwide. However, some vaccines with inadequate potency have been produced in other countries. In addition, immunization records may be difficult to interpret or have dates that appear inaccurate, causing concern that the records may not be valid and accurately reflect protection. Therefore, for children who do not have a record or who have an unknown or uncertain immunization status, serologic testing and reimmunization are both reasonable approaches. If serologic testing is not or cannot be done, any immunizations that are not documented or do not adhere to the U.S. or WHO standards should be repeated.

*References 3, 4, 14, 16, 28, 63.

TABLE 232-3 **Serologic Testing for Verifying Immunization or Past Infection**

Age	Test	Protective Level
Children ≥5 Months of Age		
Diphtheria antibody (IgG)	ELISA	>0.10 IU/mL
Tetanus antibody (IgG)	ELISA	>0.10 IU/mL
Poliovirus antibody (serotypes 1–3)	Neutralizing Antibody	Detectable antibody
Hepatitis B surface antibody (IgG)	ELISA	≥10 mIU/mL
Haemophilus influenza type b, (IgG) polyribosylribitol phosphate antibody	ELISA	≥1.0 IU/mL
Children ≥12 Months of Age		
Rubeola (measles) antibody (IgG)	IFA or ELISA	*
Mumps antibody (IgG)	IFA or ELISA	*
Rubella antibody (IgG)	ELISA	*
Varicella antibody (IgG)	ELISA	*
Hepatitis A antibody (Total or IgG)	EIA	*

*Value for positive result varies by test and laboratory.

For children whose immunizations are not up-to-date, but who have a valid, written immunization record for the vaccines documented, vaccines as recommended for their age should be administered. For children without documentation of immunizations or who have a record that does not adhere to U.S. or WHO standards, a new vaccine schedule may be initiated or measurement of antibody concentrations to any or all of the following vaccine antigens can be done: diphtheria, tetanus, poliovirus (each serotype), measles, mumps, rubella, varicella, and hepatitis A (Table 232-3). Hepatitis B serology will be done to assess the child's hepatitis B status, which will also allow for determination of immunity. *Haemophilus influenzae* type b polyribosylribitol phosphate antibody also can be done; however, fewer data exist to support this testing to determine protection. Testing for measles, mumps, rubella, varicella, and hepatitis A should only be done in children older than 12 months of age because of the possible presence of maternal antibody. Because antibody testing for one vaccine may not be predictive for others, a combination of reimmunization and antibody testing also can be used. Serologic testing is not recommended for making vaccine decisions for pertussis, pneumococcus, or influenza. Because there are not reliable correlates of protection for pertussis, diphtheria and tetanus levels may be used to guide decision making. Age-appropriate immunization for conjugate pneumococcal and influenza vaccines is recommended.

Some caveats for interpreting antibody results should be reviewed. First, in general, antibody levels do not differentiate past disease from immunization. Measles, mumps, rubella, hepatitis A, varicella, and *H. influenzae* type b are prevalent in many of the countries of origin for refugees and internationally adopted children, so protective levels of antibody may be due to past immunization of infection. Poliovirus from oral poliovirus vaccine could be transmitted from another child, providing protection to children without documentation of poliovirus vaccine. For hepatitis B virus, however, serology will distinguish between past disease and immunization. The presence of anti-HBc with anti-HBs reflects past, recovered disease, whereas anti-HBs alone is due to immunization. Second, if protective antibody is found, additional age-appropriate immunizations should still be given for some vaccines. For example, if a 9-month-old infant has protective antibody for diphtheria and tetanus, the 15- and 18-month and 4- to 6-year DTaP doses should still be given. In contrast, if a 3-year-old child has protective antibody to measles, mumps and rubella, an additional MMR is not needed when the child is 4- to 6-years of age. Third, it is important to consider age, along with the antibody levels for diphtheria and tetanus. In a 3-year-old child with a protective level of 0.20 IU/mL for tetanus, a dose of DTaP should be given to boost the tetanus level and hopefully provide higher levels of protection for pertussis. Finally, if a child does not have protective antibody for measles, mumps, or varicella, two doses are needed. However, if measles and mumps antibody levels are protective and the rubella antibody is nonprotective, only one MMR is needed for rubella.

Several studies have been published examining antibody testing to verify the immunization status or immunity to vaccine-preventable diseases in internationally adopted children.* The results of these studies differ; some studies show inadequate protection, whereas others show good levels of protection. Differences in study design and laboratory methods likely account for the different results from the various studies. In the largest study to date, in internationally adopted children with three or more vaccine doses, overall protection was found to be high for diphtheria (85%), tetanus (95%), polio (93%), hepatitis B (77%), and *H. influenzae* type b (67%).[71] For children 12 months of age and older with more than one dose of measles, mumps, or rubella vaccines, 95, 72, and 94 percent, respectively, were immune. In contrast to children without documentation for a given vaccine antigen (i.e., no doses), a lower proportion of children had protective levels of antibody: diphtheria

*References 1, 13, 41, 55, 57-59, 65, 68, 71, 74, 81-83.

(69%), tetanus (76%), polio (83%), hepatitis B (42%), *H. influenzae* type b (67%), measles (58%), mumps (31%), or rubella (30%). However, many of these children were still protected, suggesting children either had a history of disease or had received vaccines and did not have documentation. In that same study, 33 percent of adoptees had protective levels of varicella antibody (with or without vaccine documentation); 83 percent of children with a history of varicella had protective antibody. Few data exist on verifying immunization status by antibody testing in refugees. In one study, screening for varicella antibody in individuals older than 5 years of age was found to be more cost-effective than providing immediate vaccine.[33]

CONCLUSION

Providing care for refugees and internationally adopted children can be rewarding. Screening for infectious diseases and determining immunization needs is critical not only for the health and prevention of disease in these immigrants but also for the prevention of disease in their families and communities.

CHAPTER 233

Antibiotic Resistance

Philip Toltzis • Jeffrey L. Blumer

Soil bacteria developed mechanisms of resistance to antibiotics millions of years ago as a means of protecting themselves against other antibiotic-producing microorganisms or their own antimicrobial products. The current crisis of antibiotic resistance, however, was prompted by the intense selective pressure posed by the worldwide use of antibiotics during the past half-century. The problem of antimicrobial resistance in humans has been exacerbated by the widespread administration of antibiotics to farm animals.[270,409,467] Resistant zoonotic bacteria selected by this practice contaminate the food supply and thereby spread to human consumers.

To understand antibiotic resistance fully, one must make a distinction between the in vitro phenomenon of resistance and the less frequently observed clinical consequences of this in vitro phenomenon. Much of the discussion of bacterial resistance to antibiotics derives from the apparent changes in susceptibility of pathogenic bacteria to the concentrations of antibiotic achieved in blood after standard antibiotic dosing.[177] These concentrations have been established as "breakpoints" based on an integration of data derived from both clinical and animal studies, along with the measurement of plasma and serum drug concentrations associated with successful outcomes. Unfortunately, such breakpoints are not absolute. Rather, they depend on an intricate interrelationship between the pharmacokinetics and pharmacodynamics of the drug in question.[63] As such, if one component of this complex interrelationship is changed, the apparent breakpoint distinguishing susceptibility from resistance possibly and most likely also will change. Consequently, in presenting information concerning the mechanisms of antibiotic resistance and their clinical contexts, one must remember that the discussion derives, in part, from certain artificial pretexts. Any changes in a drug-dosing paradigm (e.g., dose, infusion duration, formulation) may affect the clinical relevance of the in vitro observations dramatically.

Bacteria develop resistance to antimicrobial agents through three principal cellular mechanisms (Table 233-1). In some microorganisms, two or more mechanisms of resistance to a given agent exist simultaneously. Antibiotic-resistance genes may be encoded either on the bacterial chromosome or on extrachromosomal DNA. The spread of antibiotic resistance among bacteria has been facilitated by the inclusion of many resistance genes on transmissible extrachromosomal genetic elements. To date, three interrelated genetic elements have been implicated in the expression and spread of antibiotic resistance, namely, *plasmids*, *transposons*, and *integrons*.

Plasmids are composed of circular double-stranded extra-chromosomal DNA. Although plasmids characteristically use bacterial DNA polymerase to replicate, their replication occurs autonomously.[432] Many different plasmids exist in nature; they vary in size, in the complexity of their genetic machinery, in their host range and ability to conjugate, and in their stability within the bacterium. Minimal plasmids (replicons) contain genetic sequences encoding the site at which their replication begins and sequences that determine the copy number produced per cell. However, many more genetic elements can be inserted into the replicon. Indeed, plasmids range in size from 1 kb to more than 400 kb; additional genetic machinery is required for conjugation, and, therefore, conjugative plasmids are at least 30 kb.[392] Groups of plasmids containing homologous replicative sequences generally are unable to be maintained in the same bacterial cell. This property has been exploited to categorize plasmids into different "incompatibility groups."

Recognition of the importance of plasmids to human disease increased substantially when researchers discovered that these elements could incorporate one or more antibiotic-resistance genes. These so-called resistance plasmids are found in a wide variety of gram-positive and gram-negative bacteria and encode determinants conferring resistance to many antibiotics. Resistance-conferring sequences producing resistance to several drugs may be included on the same plasmid, and multiple, different plasmids expressing different determinants can be included in the same microorganism.[33,432] Several additional classes of plasmid-borne determinants besides antibiotic-resistance genes can confer selective advantage to the bacterium. These determinants include genes rendering resistance to environmental heavy metals (e.g., mercury, antimony, arsenic, and silver) and a variety of toxic organic compounds (e.g., camphor and toluene), genes leading to the synthesis of virulence factors such as adhesion ligands promoting bacterial attachment to epithelial surfaces and those encoding exotoxins, and genes encoding compounds enabling acquisition of chemicals necessary for bacterial survival (e.g., siderophores).[432] The coexistence of these genes on plasmids carrying antibiotic-resistance determinants serves to maintain the plasmid, even in the absence of antibiotic exposure.

Plasmids are transmitted from microorganism to microorganism both vertically and horizontally.[432] Vertical transmission occurs during bacterial division as the plasmids segregate to each daughter cell. Horizontal transmission is affected through conjugation, the transmission of the plasmid from one bacterium to another.

TABLE 233-1 Cellular Mechanisms of Antibiotic Resistance and Their Transfer

Mechanisms
Genes that encode enzymes that modify or degrade antibiotics
Genes that modify the molecular targets for antibiotics
Genes that code for changes in cell wall channels or active pumping mechanisms
Transfer
Plasmids: extrachromosomal genetic elements made of circular double-stranded DNA <10 to >400 kb pairs; autonomous, self-reproducing; may be conjugative or nonconjugative
Transposon: a mobile genetic element in the bacterial chromosome or plasmid that confers a recognizable phenotype characteristic; incapable of self-replication
Integrons: DNA sequences on bacterial chromosome or plasmid often linked to a resistance gene that facilitates recombination among nonhomologous DNA sequences

At a minimum, all conjugal plasmids encode a genetic sequence that serves as the origin of transmission, and most encode additional mobilization genes.[430] However, plasmids that are unable to conjugate on their own frequently are able to do so when a conjugal plasmid co-resides in the same cell.[432] Especially in gram-negative bacteria, the donor-recipient contact required for conjugation is effected through sex pili. Conjugation frequently is restricted to intragenus transfer, but conjugation across bacterial genera may occur, particularly in gram-negative organisms, and conjugation occasionally occurs across Gram-stain barriers.[265,430]

A second group of bacterial nucleic acid elements that carry antibiotic-resistance genes is termed *transposons*. Transposons move segments of nucleic acid from one location to another, such as from different sites on the bacterial chromosome or from chromosome to plasmid.[386,393] Unlike chromosomal and plasmid DNA, transposons do not replicate independently and therefore must be integrated into a molecule capable of replication to propagate. Antibiotic-resistance genes may be encoded on conjugative transposons, which, unlike nonconjugative transposons, are able to transfer from one bacterium to another.[393] Most antibiotic-resistant conjugative transposons characterized to date have been identified in gram-positive organisms, although transposons in *Bacteroides* have been well characterized and transposons in some facultative gram-negative bacteria have been discovered as well.[380] Conjugative transposons are very promiscuous in two senses. First, they move easily from one species of bacterium to another.[380,393] Second, the integration of transposons into other nucleic acid elements is relatively sequence nonspecific. Although a preference exists for integrating into host DNA sequences with long stretches rich in adenine and thymidine, integration of conjugative transposons targets no detectable consensus sequences.[380]

Intracellular shuttling of a transposon from DNA to DNA begins with the production of a staggered cut on either side of the transposon sequence to produce single-stranded overhangs. These overhang sequences (termed *coupling sequences*) join covalently to produce a circularized double-stranded intermediate that contains the non–base-paired coupling sequences derived from opposite ends of the transposon.[380,393] Integration of the circle into the target double-stranded DNA also results in flanking non–base-paired regions, which become complementary only after a round of replication occurs.[393] Conjugation of the transposon from cell to cell also begins with the circularized intermediate, which, after nicking at a presumed origin site, is transferred as a single strand from donor bacterium to recipient bacterium, whereupon it recircularizes. Complementary strands then are added to both single strands in the donor and the recipient, and integration into target DNA in both cells ensues.[380]

Excision and integration of transposons are catalyzed by a transposon-encoded integrase.[380,393] The efficiency of excision varies widely and accounts for the differences in rates of transfer of transposons. Conjugation of many transposons appears to be regulated.[380] Unlike some plasmids, conjugative transposons do not exclude entry of other transposons.[380] Indeed, some transposons promote the conjugation of other transposons as well as co-resident plasmids; the result is the dissemination of resistance determinants that are not encoded on the transposon itself.[393]

Integrons, a third type of bacterial DNA important in antibiotic resistance, are composed of segments of DNA that are able to capture and excise gene cassettes coding antibiotic-resistance genes. Integrons are unable to transfer from bacterium to bacterium themselves. To disseminate, the integron first must insert into a plasmid or transposon.[108,342,354] So-called superintegrons, carrying more than 50 gene cassettes, have been identified on the chromosomes of some nonpathogenic environmental bacteria.[264] Superintegrons possess many of the organizational features of antibiotic-resistance integrons and may have been their progenitors. Integrons contain an integrase that catalyzes the incorporation and excision of the cassette into the integron, as well as a promoter that mediates the expression of the resistance determinant, both situated 5′ to the cassette. The cassettes themselves are small segments usually encoding a single antibiotic-resistance determinant. Cassettes have been identified that confer resistance to a broad range of antibiotics, including the β-lactam agents, the aminoglycosides, fluoroquinolones, trimethoprim (TMP), and chloramphenicol.[108,342,354] At the 3′ end of each cassette is a variable region commonly termed the *attC site* or, alternatively, the *59-bp element*, although it varies in length from cassette to cassette from 57 bp to more than 100 bp.[264] This 3′ element contains the sequences recognized by the integrase for incorporation of the gene cassette into the integron.[264,354] Several classes of integrons have been defined, based on the sequence of the integrase and their preference for certain transposons. Most antibiotic-resistance integrons are derived from class 1.[264] A single integron may contain multiple antibiotic-resistance cassettes in tandem, all of which are controlled by the single integron promoter. Transcription of tandem cassettes may terminate prematurely, however, such that the cassettes closest

to the integron promoter are transcribed at the highest level.[342,354]

The consequences of mobile resistance genes on plasmids and transposons cannot be overstated. They have given bacteria a profound replicative advantage in the age of antibiotics by enabling the instant acquisition of multiple, ready-made antibiotic-resistance genes without requiring each organism to independently undergo the same or similar resistance-conferring mutations again and again.[264] Hence, bacteria may become resistant almost immediately after exposure to antibiotics and may efficiently transmit this resistance to bacteria co-residing in the same host and to bacteria colonizing or infecting multiple hosts in the same community.

RESISTANCE TO SPECIFIC ANTIBIOTICS

β-Lactam Antibiotics

The β-lactam antibiotics are a diverse, highly effective family of drugs with broad activity against a wide variety of hospital- and community-acquired pathogens. The β-lactams are composed of four subgroups, namely, the penicillins, the cephalosporins, the monobactams, and the carbapenems. Resistance to the β-lactams is mediated by one of two principal mechanisms: (1) production of enzymes capable of hydrolyzing the β-lactam ring and (2) alteration of the target bacterial molecules, the penicillin-binding proteins (PBPs).

β-Lactamase Production

Clinical Relevance. The explosive development in antimicrobial therapeutics since the mid-20th century has been driven, to a great extent, by the impact of β-lactamase activity on the response to antibiotic therapy in the clinical setting.[357] Shortly after penicillin became incorporated into the clinical armamentarium for the treatment of systemic infections, clinical failures were reported in patients treated for infections caused by *Staphylococcus aureus*. On further analysis, these failures were attributed to the presence of an enzyme, "penicillinase," elaborated and excreted by the bacteria, that inactivated the antibiotic before it could manifest its clinical effect. This finding led to the development of numerous new antistaphylococcal penicillins (i.e., the isoxazolyl penicillins) that were not substrates for this enzyme.

At the same time, a newer class of β-lactam agents, the cephalosporins, was developed. One of the criteria employed in moving candidate drugs from this class to the clinic was their resistance to inactivation by the penicillinase elaborated by staphylococci. Further development of all four of the subgroups in the β-lactam family (i.e., penicillins, cephalosporins, monobactams, and carbapenems) was influenced significantly by the recognition that the penicillinase elaborated by staphylococci was representative of a larger class of enzymes that were also present in gram-negative organisms. In this regard, history repeated itself. As gram-negative organisms such as *Escherichia coli* emerged as important clinical pathogens, their emerging resistance to aminopenicillins on the basis of β-lactamase elaboration spawned the development of a group of enzyme inhibitors including clavulanic acid, sulbactam, and tazobactam.[241,361] Moreover, even as it became necessary to expand the spectrum of both the penicillins and cephalosporins to include some of the more itinerant gram-negative organisms such as *Serratia* spp., *Enterobacter* spp., and even *Pseudomonas*, β-lactamase stability emerged as a necessary attribute for clinical success.[241,361] This expansion was accomplished either through the addition of one of the β-lactamase inhibitors to members of the carboxy and acylureido class of penicillins or through structural engineering such as that seen with the development of the second- and third-generation cephalosporins and carbapenems.

In pediatric practice, the importance of β-lactamase became apparent soon after the widespread use of antibiotics in hospitalized patients began. However, three sentinel clinical events were probably most responsible for establishing β-lactamase as a prominent pediatric clinical problem. In 1974, the first case of bacterial meningitis caused by ampicillin-resistant *Haemophilus influenzae* type b was reported.[296,429] This report resulted in marked changes in clinical practice. First, all infants and children with suspected bacterial meningitis were treated empirically with both ampicillin and chloramphenicol (a drug not susceptible to degradation by bacterial β-lactamase) instead of with ampicillin alone.[357] In addition, several newer antibiotics, particularly the second- and third-generation cephalosporins, were evaluated for their efficacy in this clinical setting. From these studies, ceftriaxone or cefotaxime emerged as the drug of choice for the empirical treatment of suspected or proven bacterial meningitis in children. This selection was based both on both greater potency against *H. influenzae* type b and β-lactamase stability.

The second circumstance resulting in the affirmation of β-lactamase as an important clinical problem in pediatrics was the recognition of *Moraxella catarrhalis*, a β-lactamase–producing organism, as the third leading cause of acute otitis media in infants and children, and the emergence of amoxicillin resistance among the nontypeable strains of *H. influenzae*. β-Lactamase production in *H. influenzae* was thought to be particularly associated with therapeutic failure, thus spawning the development of oral second- and third-generation cephalosporins and newer macrolides as therapeutic alternatives in childhood otitis media.

By the early 1980s, β-lactamase–producing bacteria garnered additional attention from pediatricians because of the role of these bacteria as nosocomial pathogens. These bacteria became prominent as children with severe but survivable conditions (e.g., hematologic malignancies and solid organ transplantation) required immunosuppressive therapy and prolonged hospitalization, both of which predisposed these children to acquisition of hospital-acquired infection. With each succeeding decade, the number and variety of β-lactamase–producing hospital-acquired bacteria increased. By the early 21st century, virtually all nosocomial *S. aureus*, coagulase-negative staphylococci, and enteric and nonenteric gram-negative pathogens elaborated β-lactamase. These organisms commonly encode multiple distinct

β-lactamases and express them simultaneously. Consequently, many bacterial infections currently acquired in the hospital are resistant to all β-lactam agents except for the higher-generation β-lactam– β-lactamase inhibitor combinations, the advanced-generation cephalosporins, or the carbapenems. In the most extreme cases, particularly in *Pseudomonas*, *Acinetobacter*, and carbapenem-resistant Enterbacteriaceae infections, the organisms are resistant to all available β-lactam drugs.[61,228,346]

Mechanism of Resistance. The β-lactamases constitute a broad array of enzymes that hydrolyze the β-lactam ring of selected antibiotics (Fig. 233-1). Most β-lactamases are structurally similar to the PBPs, and the consensus is that at least some of the β-lactamases were derived evolutionarily from them.[276] β-lactamases can be identified in both gram-positive and gram-negative bacteria. In gram-positive bacteria, the enzyme is secreted into the cell-free environment, whereas in gram-negative organisms, most of the enzyme is confined and concentrated in the periplasmic space between the cell wall and the outer membrane.

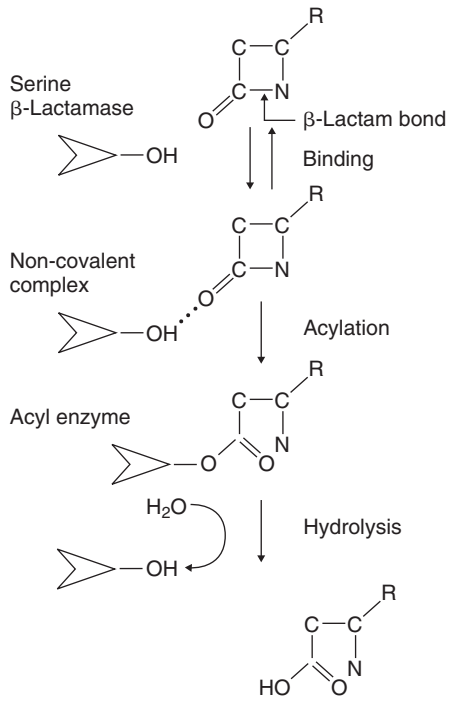

FIGURE 233-1 ■ Mode of action of β-lactamases (classes A, C, and D).

Nearly 1000 β-lactamases have been characterized,[38,185] and, doubtless, many more exist in nature. The β-lactamases have been categorized variously according to substrate preference, isoelectric focus, whether they are encoded on the bacterial chromosome or an episome, their ability to be inhibited by clavulanate, and their molecular structure. The molecular classification of Ambler[4] proposed in the 1980s is still widely employed. This classification divides the β-lactamases into four categories, A through D, although all but B, the metalloenzymes, have proved to have similar three-dimensional conformations.

The classification system of Bush, Jacoby, and Medeiros, proposed in 1995[39] and updated by Bush and Jacoby in 2010[38] divides these enzymes into three groups (with subcategories) and uses virtually all the properties listed earlier to discriminate one class of enzyme from the others. The properties of these groups are outlined in Table 233-2 and are described more fully here.

Group 1 AmpC β-Lactamases. The group 1 enzymes (also referred to as AmpC β-lactamases) hydrolyze virtually all β-lactam antibiotics except the carbapenems and are resistant to inhibition by clavulanate. These enzymes typically are chromosomally encoded on a sequence labeled *amp*C in a wide range of gram-negative bacteria; however, the AmpC β-lactamases are expressed in quantities sufficient to produce clinically important resistance only in selected species, including *Enterobacter cloacae*, *Serratia marcescens*, *Citrobacter freundii*, *Pseudomonas aeruginosa*, and *Morganella morganii*. In the absence of drug exposure, expression of the group 1 AmpC β-lactamases in these species is repressed by an upstream sequence labeled *amp*R (Fig. 233-2).[276,334] However, exposure of the bacteria to a β-lactam leads to the production and intracellular incorporation of a bacterial cell wall metabolite that itself is processed by the enzyme AmpD.[180,239] In sufficient quantity, the AmpD substrate interacts with *amp*R, thus reversing the repression, and relevant quantities of the AmpC β-lactamase are thereby synthesized.

β-lactam antibiotics differ in their ability to induce AmpC β-lactamases by this mechanism. Ampicillin,

TABLE 233-2 **Properties of the Major Groups of β-Lactamases**

Group	1	2	3
Ambler class	C	A, D	B
Substrate preference	All but carbapenems	Variable*	Variable (carbapenems)
Chromosomal/plasmid	C	P	C/P
Distribution	Gram negative	Gram negative/positive	Gram negative
Clavulanate inhibition	No	Yes	No
Inducible†	Yes	No	No

*May be divided into subgroups including penicillinases, cephalosporinases, cloxacillinases, and carbapenemases. Enzymes frequently can hydrolyze more than one group of β-lactam.
†Indicates that normally repressed β-lactamase production can be induced by β-lactam exposure.
Data from Bush K, Jacoby GA, Medeiros AA. A functional classification scheme for beta-lactamases and its correlation with molecular structure. *Antimicrob Agents Chemother* 1995;**39**:1211-33.

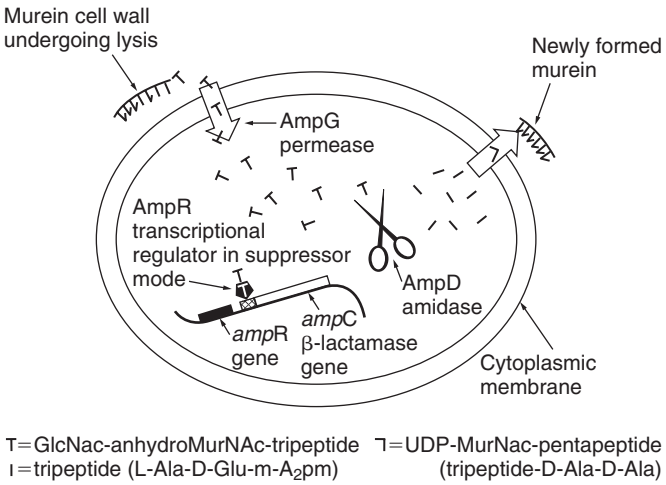

FIGURE 233-2 ■ A model for peptidoglycan recycling and β-lactamase induction in enterobacteria. The lytic transglycosylases in the periplasm cleave the bond between *N*-acetylglucosamine (GlcNac) and *N*-acetylmuramic acid (MurNac) and form the peptidoglycan degradation product, *N*-acetylglucosaminyl-1,6-anhydro-*N*-acetylmuramyl-L-alanyl-D-glutamyl-meso-diaminopimelic acid (T). The AmpG permease transports T into the cytoplasm. The AmpD amidase recognizes specifically substrate containing anhydromuramic acid and cleaves the bond between it and L-alanine, releasing the stem tripeptide, L-Ala-D Glu-m-A_2pm (I). Unprocessed T activates the AmpR transcriptional regulator, thereby inducing β-lactamase production. The tripeptide, I, conversely, recycles to form new peptidoglycan. By regulating the relative amounts of T versus I, AmpD may control peptidoglycan composition. The regulatory function of the AmpC β-lactamase, if any, is unknown.

cefoxitin, and imipenem are potent inducers, whereas most of the third-generation cephalosporins are weak. However, spontaneous mutations leading to a dysfunctional AmpD enzyme that occur at high frequency in nature result in permanent de-repression of the *amp*C gene, which, in turn, results in constitutive production of large quantities of the AmpC β-lactamase (see Fig. 233-2). De-repressed organisms are rendered highly resistant after this single mutational step. The third-generation cephalosporins are particularly prone to selecting such AmpD mutants, and the clinical emergence of resistant de-repressed isolates during the course of treatment with a third-generation cephalosporin has been documented.[55]

Group 2 β-Lactamases. The group 2 β-lactamases represent the largest and fastest growing group of β-lactamases owing largely to the proliferation of newer enzymes with broad substrate specificities.[38] The group 2 β-lactamases are encoded primarily on plasmids.[39,156,216,322,334] These plasmids commonly contain resistance determinants to other antibiotic classes as well. The plasmids are stable and frequently are maintained within the bacteria even in the absence of antibiotic pressure. Moreover, they can be transmitted by conjugation from organism to organism and across species, sometimes leading to a "plasmid outbreak" in a confined environment (e.g., a nursing home or intensive care unit [ICU]) that is caused by different species containing the same plasmid. The group 2 enzymes have substrate preferences that have become increasingly broad with the introduction of each new class of β-lactam antibiotic. Characteristically, the group 2 enzymes are inhibited by clavulanate and are found in both gram-positive and gram-negative bacteria (see Table 233-2).[39,216,276]

The prototypical group 2 β-lactamases are included in the TEM and SHV families of enzymes, although large numbers of group 2 enzymes not belonging to either of these families also have been characterized. TEM-1, first identified in Europe in 1963, hydrolyzed ampicillin. During the ensuing decades, the TEM sequence mutated in a stepwise fashion (with each new iteration labeled sequentially: TEM-2, TEM-3, and so on), resulting in the ability of each new enzyme to degrade an ever-increasing number of β-lactam antibiotics.[93,184,276] Many of these mutations widen a critical cavity, formed by the three-dimensional configuration of the molecule, containing a serine-active site at its bottom that is key to hydrolysis of the β-lactam.[127,185] Although these mutations render the enzymes kinetically less efficient than their parents, they allow the entry of the newer β-lactams with their bulky side chains into the cavity, thereby enabling the serine-active site at the bottom to reach the β-lactam ring.[93,276]

Extended-Spectrum β-Lactamases (ESBLs). Of increasing importance among the group 2 enzymes are the extended-spectrum β-lactamases (ESBLs). ESBL-producing organisms are distributed worldwide, but their incidence varies geographically.[332] Currently, bacteria elaborating ESBLs infect primarily critically ill, hospitalized patients,[323] although these enzymes are being reported in increasing numbers in the community.[58,281,340] Although they are molecularly diverse, ESBLs confer a common resistance phenotype, namely, reduced susceptibility to the third-generation cephalosporins, especially ceftazidime, and to aztreonam. Susceptibility to the carbapenems is preserved.[322] Common to other group 2 β-lactamases, hydrolytic activity typically is suppressed by the β-lactamase inhibitors. Most ESBLs are molecular descendants of TEM-1 and SHV-1 and are found in *E. coli*, *Klebsiella pneumoniae*, and to a lesser extent in *Proteus mirabilis.* Other families of ESBLs have been described. Among the more important ESBLs are the CTX-M enzymes, which are particularly active against cefotaxime, and some of the OXA-β-lactamases, the principal substrate of which is oxacillin but the spectrum of which has broadened to include the advanced-generation cephalosporins including cefepime.[38,322,332,340] Concomitant with their molecular evolution, ESBLs have been identified in an ever-widening range of bacteria, including *Pseudomonas*, *Salmonella*, and *Shigella* and *Enterobacter* spp.[322]

Although most ESBL-producing bacteria are overtly resistant, the third-generation cephalosporins have minimal inhibitory concentrations (MICs) against some ESBL-producing organisms that fall into the high end of the susceptible range. Consequently, the incidence of ESBL-producing bacteria is underestimated when conventional MIC breakpoints for resistance are used. Growing numbers of reports, however, indicate that infections caused by organisms expressing these "susceptible" MICs are clinically unresponsive to the third-generation cephalosporins.[352] Many hospital microbiology laboratories therefore screen all *E. coli*, *Klebsiella*, and

P. mirabilis clinical isolates for reduced susceptibility to both ceftazidime and cefotaxime and alert the clinician accordingly. Although the optimal therapy for infection caused by ESBL-producing, gram-negative bacteria is not established, many authorities recommend a carbapenem.[185,322,352]

Carbapenemases. The latter half of the 2000s witnessed the alarming spread of a new set of group 2 β-lactamases composed of carbapenemases, including the enzyme labeled "*Klebsiella pneumoniae* carbapenemase (KPC)"[28,30,167,407,474] and advanced-generation OXA β-lactamases that can hydrolyze carbapenems. This phenomenon has undermined the effectiveness of the class of antibiotics that had become the therapy of choice for previously encountered highly resistant organisms expressing Amp C β-lactamases and ESBLs.

KPC was first identified in an isolate of *K. pneumoniae* in the late 1990s from a patient in North Carolina.[28,167,407,474] Because of the presence of KPC on readily transmissible and promiscuous genetic elements, organisms expressing this enzyme spread rapidly up the American Atlantic Coast. By the mid 2000s, KPC-bearing *K. pneumoniae* had caused a city-wide epidemic among hospitalized patients in New York City[347]; soon thereafter, they were discovered in Europe, South America, the Middle East, and the Far East.[41,117,159,345,347] To date, infections by KPC-expressing organism have been identified primarily in critically ill adults in acute care hospitals[120,142,317] and residents of long-term care facilities,[52,328,473] without a significant representation in community-acquired disease. The organism has been reported only sporadically in children,[242] but their presence in the pediatric age group may be underappreciated. A survey of resistant organism-colonization in a long-term care facility for neurologically impaired children and young adults in Ohio, for example, revealed an unrecognized high prevalence of KPC colonization among the residents.[451]

Virtually all reports document that infection by a KPC-bearing bacterium is associated with increased risk for death, with crude mortality frequently around 50 percent.[242,410,441] In vitro data and clinical experience in adults have indicated that treatment with at least two agents is better than monotherapy, including regimens containing a carbapenem when the MIC is in the lower range.[188,349,441,484] Unfortunately, organisms expressing KPC are almost always multidrug resistant. Tigecycline and colistin are the antibiotics with the most consistent activity,[142] although some strains have emerged resistant to colistin.[24,290]

The KPCs are extraordinarily broad-spectrum enzymes, able to hydrolyze every class of β-lactam. Like other group 2 β-lactamases, the KPC enzymes have a serine-based active site for hydrolysis of the β-lactam ring. Their broad activity likely is the result of a more shallow position of the catalytic active site within the enzymatic cavity, rendering it more accessible to its antibiotic substrates.[347] However, unlike the other group 2 β-lactamases they are not sensitive to β-lactamase inhibitors; in fact, some data suggest that KPC enzymes hydrolyze inhibitors.[318,319]

The KPC family of enzymes is composed of multiple molecularly-similar homologues that have been numbered sequentially as they have been discovered and characterized.[214,347] The majority of disease to date has been caused by *K. pneumoniae* expressing KPC-2 and KPC-3. Dominant lineages of KPC-producing *K. pneumoniae* have been identified through multilocus sequence typing, a method that defines clonal relationships among bacteria by assessing polymorphisms within of a series of housekeeping genes; the sequence type ST 258 has been an especially prominent clone in the United States.[142,214] In any given geographical location, however, organisms expressing KPC can be found in a variety of *K. pneumoniae* sequence types and in species and genera of Enterobacteriaceae other than *K. pneumoniae*, indicating that KPCs have spread both by person-to-person transmission of dominant clones as well as by bacteria-to-bacteria transmission of enzyme-bearing plasmids.[214,230,261]

Newer OXA β-lactamases, particularly OXA-23 and OXA-48, also are able to degrade carbapenems. These enzymes are particularly prominent in *Acinetobacter*,[227] but they occasionally have been identified in other species.[38] Their activity is resistant to β-lactamase inhibitors. OXA-23 and OXA-48 are incorporated on a transmissible transposon, and they have been found in geographically diverse organisms.

Group 3 Metalloenzymes. The group 3 β-lactamases are composed of the metalloenzymes (see Table 233-2).[37,458] These β-lactamases are genetically heterogeneous and structurally dissimilar to those of groups 1 and 2. The metalloenzymes are not suppressed by β-lactamase inhibitors. The active site requires the participation of zinc; hence hydrolysis of the β-lactam ring is inhibited by chelators such as ethylene diaminetetraacetic acid (EDTA). The active site itself is composed of a wide plastic groove that can accommodate many β-lactam substrates. Some metalloenzymes are chromosomal (e.g., in *Stenotrophomonas*), but many have been identified on integrons that are inserted on transferable elements.[458] These latter metalloenzymes, which characteristically encode aminoglycoside-resistance determinants as well, are identified primarily in *Pseudomonas* and *Acinetobacter* spp. and selected Enterobacteriaceae. During the latter 1990s and early 2000s, organisms harboring transferable metallo-β-lactamases, particularly those from the IMP and VIM family of metalloenzymes, were identified in many countries in eastern Asia, Europe, and South America and in smaller numbers in the United States.[347] In 2008, a new plasmid-borne metallo-β-lactamase was identified in Western Europe labeled "New Delhi metallo-β-lactamase" (NDM) in patients who had previously been hospitalized in India.[223] Organisms harboring NDM subsequently were isolated throughout the Asian subcontinent and the United Kingdom. Bacteria expressing this metalloenzyme have been identified in patients in all age groups, including children, and in some instances have been the cause of community-associated infection.[223] The substrate preference of the metallo-β-lactamases varies, but most organisms expressing these enzymes have reduced susceptibility or overt

resistance to all the β-lactam antibiotics, including the carbapenems. Moreover, organisms encoding a metalloenzyme frequently express other chromosomal and plasmid-encoded β-lactamases as well, and this phenomenon, coupled with the coincident expression of resistance to other classes of antibiotic, often severely limits therapeutic options.

Although the properties summarized in Table 233-2 apply to most of the enzymes in each group, many exceptions have been noted. For example, enzymes that are genetically homologous to the group 2 family, typically plasmid-borne enzymes, have been identified on the bacterial chromosome in some isolates of *S. marcescens* and *E. cloacae*.[276] Conversely, group 1 AmpC enzymes, typically contained on the bacterial chromosome, have been identified on plasmids in genera such as *Klebsiella* and *Salmonella* that customarily do not express chromosomal *ampC* β-lactamase.[332-334] Some rare group 2–type enzymes are inducible.[276] TEM-type enzymes that are resistant to clavulanate have been identified (the so-called inhibitor-resistant TEMs [IRTs]).[47,207]

The degree of resistance exhibited by an organism encoding a β-lactamase frequently depends not only on the enzyme's in vitro substrate specificity and kinetics but also on the amount of enzyme produced. Hyperproduction of β-lactamase usually is the result of some alteration of a controlling sequence or an increase in number of copies of the β-lactamase gene within the bacterium.[126,315,479] High-level resistance results, and the susceptibility of the organism diminishes with increasing numbers of bacteria. Consequently, the organism may appear clinically unresponsive to a β-lactam antibiotic if hyperproduction occurs in the context of a high-inoculum disease. In some circumstances, hyperproduction operates in concert with other mechanisms to derive a resistant phenotype. Thus, some isolates of *E. cloacae* and *P. aeruginosa* have been rendered carbapenem resistant through a combination of hyperproduction of an AmpC β-lactamase, which normally is ineffective in hydrolyzing the carbapenems, and the simultaneous loss of the outer-membrane poron through which imipenem traverses to reach the PBP.[50,197,292,346]

Alteration of Penicillin-Binding Proteins

Clinical Relevance. Two species of clinical importance to pediatricians express resistance to β-lactam drugs through the alteration of PBPs, namely, penicillin-resistant *Streptococcus pneumoniae* and methicillin-resistant *Staphylococcus aureus* (MRSA). Indeed, not until penicillin-resistant *S. pneumoniae* was recognized did pediatricians begin to realize that alterations in the PBPs in the bacterial cell wall could pose a major clinical problem.[201,267] However, to date, the precise clinical importance of these organisms remains unclear.

Part of the problem in assessing the clinical importance of altered penicillin binding among pneumococci is that, rather than simply conferring penicillin resistance, the genes coding for this altered enzyme activity often co-segregate with genes coding for resistance to other antibiotics, such as TMP-sulfamethoxazole (TMP-SMX) and the macrolides.* Thus, unlike resistance associated with the elaboration of β-lactamase, in which simply selecting a different class of antibiotic often will provide a reasonable solution, resistance associated with alteration in PBPs is multifarious and, if clinically important, may require significant alterations in clinical practice to provide an effective antimicrobial regimen. The more limited menu of antibiotic choices for the treatment of infections caused by these organisms led to some interesting therapeutic conventions. For example, because the basis for this type of resistance is akin to altered enzyme affinity, investigators recognized in the mid 1990s that overcoming the apparent decrease in efficacy could be possible by simply increasing the dose of β-lactam employed.[201,268,269] Of the available agents, only amoxicillin had the requisite therapeutic index to support the increased dosing strategy. On this basis (almost exclusively), the high-dose amoxicillin regimen (80 to 100 mg/kg/day) that is currently recommended was adopted. Additionally, the perceived need for a drug effective against antibiotic-resistant *S. pneumoniae* led to the widespread use of the parenteral third-generation cephalosporin, ceftriaxone, in the setting of common upper and lower respiratory tract infections because of its in vitro activity against most of these organisms.

As the clinical impact of the emergence of the antibiotic-resistant *S. pneumoniae* has been examined more carefully in recent years, several trends have emerged.[201,478] In immunocompetent patients with pneumonia and most other non–central nervous system pneumococcal infections, no difference appears to exist in outcomes between patients infected with organisms that are susceptible to penicillin and those infected with organisms showing decreased susceptibility to penicillin.[314,331] Moreover, apparently no association exists between the intrinsic virulence of the organism and its antibiotic susceptibility. In contrast, in patients with pneumococcal meningitis caused by organisms with decreased penicillin susceptibility, there appears to be a delay in sterilization of cerebrospinal fluid in the presence of standard treatment.[247,477] For this reason, the current recommendation for empirical treatment of bacterial meningitis in infants and children consists of a combination of ceftriaxone or cefotaxime and vancomycin until the organism is identified and its antibiotic susceptibility is known.

S. pneumoniae remains the most prevalent bacterial cause of acute otitis media in infants and children. The clinical importance of the antibiotic susceptibility of these organisms in this clinical setting remains difficult to ascertain. The infection has a high rate of spontaneous resolution, and virtually all treatment is provided on an empirical basis. Consequently, any improved cure rate related to altered prescribing practices aimed at greater activity against organisms with decreased antibiotic susceptibility would be difficult to substantiate. Finally, the importance and virulence of these organisms in children who are either immunocompromised or immunosuppressed remain to be determined unequivocally.

*References 51, 75, 82, 83, 182, 358, 434.

The problem of penicillin-resistant *S. pneumoniae* was at least partially addressed by the introduction of the conjugated heptavalent pneumococcal vaccine (PCV7) in 2000. The serotypes included in the vaccine accounted for most penicillin-resistant pneumococci in the United States at that time.[435] Surveys conducted by the Centers for Disease Control and Prevention (CDC) indicated that the incidence of invasive *S. pneumoniae* infection caused by penicillin-resistant strains decreased by more than 50 percent in the years immediately following introduction of the vaccine.[224] The decrease was most pronounced in children younger than 2 years of age, but the herd immunity created by universal PCV7 immunization resulted in a reduction of pneumococcal infection in all age groups. This benefit was mitigated in part by increases in disease caused by resistant serotypes not included in the vaccine, most notably serotype 19A.[18,224] In response to this phenomenon, a 13-valent conjugated pneumococcal vaccine (PCV13) was licensed in the United States in 2010; it included all seven serotypes represented in PCV7, plus six additional serotypes, including 19A, that accounted for the majority of residual invasive and antibiotic-resistance pneumococcal infection encountered during the post-PCV7 era. Licensure of PCV13 was based on studies documenting immunogenicity rather than protective efficacy,[320,426] and hence the effectiveness of PCV13 in further reducing the circulation of antibiotic-resistant pneumococcal strains has yet to be established.

MRSA was isolated first from hospitalized adult patients in 1961 and became a prominent pathogen in critically ill patients during the ensuing decades. By the early 2000s, more than half of *S. aureus* infections in patients in ICUs in the United States were caused by MRSA.[293] Compared with those in adults, MRSA infections among hospitalized children occur relatively infrequently. In the mid 1990s, however, MRSA infections were identified among otherwise healthy children with no prior contact with hospitals or hospitalized patients.[157,175] These strains of community-associated MRSA (CA-MRSA) were molecularly distinct from MRSA infections previously identified in the hospital environment. By the mid-to-late 2000s, CA-MRSA had established a worldwide presence in both children and adults.[3,300] These organisms cause primarily skin and soft tissue infection but occasionally bone and joint infection, severe necrotizing pneumonia, and other invasive, deep tissue disease. CA-MRSA infections are especially common in populations inhabiting close quarters and engaging in skin-abrading activities, including athletes participating in competitive sports, military personnel, and prison populations.[461] Additionally, they increasingly are being identified in patients acquiring their infection in the hospital,[172,344] blurring the epidemiologic distinctions that had once characterized HA-MRSA and CA-MRSA lineages.

Most MRSA isolates, both hospital and community associated, are derived from a relatively small number of prominent, widely disseminated clones.[307] Several systems have been proposed to categorize the principal MRSA lineages. The system established by the CDC is based on *Sma*I macro-restriction patterns of bacterial DNA visualized after separation by pulse-field gel electrophoresis (PFGE). The PFGE types so defined have been labeled USA100 through USA1200.[79,178,272] Currently, the marked majority of MRSA strains derived from patients in the United States fall within one of these PFGE types.[79,272] Most American CA-MRSAs are included in the USA300 group, particularly those falling in the subgroup labeled USA300-114, with a minority derived from the USA400 and USA1100 groups.[213,300,395] HA-MRSA strains are derived from most of the remaining pulsed-field types. MRSA strains additionally have been categorized by multilocus sequence typing, a technique that distinguishes bacterial lineages based on polymorphisms found in a series of housekeeping genes, with the predominant American strain USA300-114 belonging to sequence type ST 8.[300] Elsewhere in the world, community-associated MRSA is represented by other PFGE-types and multilocus sequence types, although variants of the USA300 strain are common in Canada and Latin America.[300]

Mechanism of Resistance. β-Lactam antibiotics must bind to PBPs to confer their activity, and alteration of the structure of PBPs results in diminished affinity for drug and, consequently, antibiotic resistance. The PBPs are a heterogeneous group of compounds normally responsible for maintaining the peptidoglycan matrix supporting the bacterial cell wall. PBPs vary from species to species in number, size, copy number per cell, and affinity for β-lactam agents.[124,146,383] Typically, four to eight PBPs are present in any given bacterial isolate; they range in molecular weight from 35 to 120 kd.[124] PBPs possess two principal enzymatic activities. In general, the larger PBPs are responsible for peptidoglycan transpeptidase activity, whereas the smaller PBPs usually carry D,D-carboxypeptidase activity.[124] These activities constitute the final reactions in the formation of the peptidoglycan matrix and are responsible for the cross linkage that significantly adds to the tensile strength of the bacterial cell surface.

Examination of PBP-mediated β-lactam resistance in *S. pneumoniae* and *S. aureus* serves to exemplify some of the features of this mechanism of resistance. Detailed investigations indicate that penicillin resistance in pneumococcus is associated with alternations in PBP 1A, 1B, 2A, 2X, and 2B; cephalosporin resistance has been correlated with structural abnormalities in PBP 1A, 2A, and 2X.* Confirmation that the resistant phenotype is related directly to structural abnormalities in various pneumococcal PBPs has been achieved through transformation experiments.[15,57,135,289] In these studies, penicillin-susceptible strains are converted to penicillin-resistant strains by addition of amplified DNA encoding the putative resistant PBPs. Patterns of PBPs from resistant pneumococci vary considerably from geographic location to location, a finding indicating that PBP-related pneumococcal resistance probably arose independently in various parts of the world.[145]

PBPs from penicillin-resistant *S. pneumoniae* contain blocks of amino acid sequences that are remarkably

*References 15, 57, 135, 145, 147, 289.

divergent from those seen in susceptible pneumococci. These sequences are homologous to those encoding for PBPs from other streptococcal species (e.g., *Streptococcus oralis* and *Streptococcus mitis*), a finding suggesting that the resistant pneumococci contain mosaic PBPs that arose after transformation and recombination of homologous genes from closely related bacteria.[89,90,144,226] These sequences then developed point mutations conferring resistance. A similar pattern of "resistance blocks" of amino acids has been identified in the PBPs of penicillin-resistant *Neisseria gonorrhoeae*, which appear to have originated from other *Neisseria* spp.[146] The degree of resistance conferred by a single mutated PBP is relatively small.[124,135] Acquisition of multiple abnormal PBPs results in incremental resistance and, ultimately, an organism that can survive routine β-lactam therapy.

Whether associated with the hospital or the community, all isolates of MRSA contain the *mecA* gene, a 2130-bp chromosomal sequence encoding the PBP 2a, which, unlike the other staphylococcal PBPs, has low affinity for β-lactam antibiotics.[67,68] The *mecA* gene is carried on a mobile element designated the *staphylococcal cassette chromosome mec (SCCmec) sequence*.[486] All MRSA strains contain an SSC*mec* complex, but their size and organization vary, thus allowing them to be grouped into eight distinct SCC*mec* types, designated by roman numerals I through VIII.[178,306,486] Most hospital-acquired (HA)-MRSA strains contain SCC*mec* types I to III, whereas CA-MRSA strains characteristically harbor type IV.[178] In most HA-MRSA isolates, the SSC*mec* sequence contains resistance determinants additional to *mec*A, including those conferring resistance to clindamycin, the aminoglycosides, and the fluoroquinolones.[72,486] Hence, these organisms possess a selective advantage in ICUs, where exposure to multiple classes of antibiotics commonly occurs. The CA-MRSA SCC*mec* type IV encodes a smaller SCC*mec* sequence usually lacking the multiple antibiotic-resistance genes found in their hospital-associated counterparts.[72,486] Although a growing number of American strains of CA-MRSA are emerging resistant to fluoroquinolones through chromosomal mutations, to date only a small minority of CA-MRSA bacteria express resistance to other antibiotics.[271,431] On the other hand, USA300 CA-MRSAs express a number of virulence factors not common in other strains. Most notable among these is the Panton-Valentine leukocidin, possibly important for soft tissue breakdown and destruction, but a host of other virulence factors, as well as altered genetic elements controlling their expression, have been identified.[431] The smaller SCC*mec* sequences allow CA-MRSA to replicate more rapidly than does HA-MRSA,[305] because they can be maintained by the bacterium at a lower metabolic cost. The relatively small size of the CA-MRSA SCC*mec* sequences further enables efficient transfer to co-colonizing susceptible *S. aureus*.[486]

SCC*mec* elements likely originated in coagulase-negative staphylococci. Type IV SSC*mec* sequences, for example, have been identified in isolates of *Staphylococcus epidermidis* from the 1970s.[471] Additionally, sequences have been found in *S. epidermidis* and *Staphylococcus hominis* strains that contain the regulatory genes and insertion sequences of the SCC*mec* elements found in MRSA but that lack the *mecA* gene itself.[3]

Macrolides, Lincosamides, and Streptogramins

Clinical Relevance

The macrolides are compounds that contain 14-member (e.g., erythromycin and clarithromycin), 15-member (e.g., azithromycin), or 16-member (e.g., spiramycin) lactone rings. Their activity is directed primarily against gram-positive organisms and some gram-negative respiratory tract pathogens. In many bacteria, resistance to macrolides occurs concomitantly with that of the structurally unrelated lincosamides (including clindamycin) and streptogramin B families of antibiotics, two classes with activity also primarily against gram-positive bacteria. Because these three families of antibiotics interact competitively for ribosomal binding, they probably are associated with the same ribosomal site.

Resistance to the macrolides was noted in staphylococcal species soon after the introduction of erythromycin. More recently, however, macrolide resistance in streptococcal pathogens, particularly *S. pneumoniae* and *Streptococcus pyogenes*, emerged and assumed major clinical importance. Macrolide resistance among pneumococci is a result of both international dissemination of resistant clones and horizontal transmission of resistance determinants.[122,372] The late 20th century witnessed dramatic increases in the incidence of macrolide resistance in *S. pneumoniae* in many areas of the world.[158] In Southeast Asia, surveys indicated that nearly 40 percent of pneumococcal isolates were resistant to all macrolide antibiotics, and samplings of organisms from Europe and the Western Hemisphere showed similar but less extreme trends.[158,211] Perhaps most troubling, resistance to macrolides among pneumococci occurred particularly frequently in isolates coexpressing resistance to penicillin and other oral antibiotics.[83,176]

Similar to penicillin-resistant pneumococcus, the prevalence of macrolide-resistant *S. pneumoniae* has been reduced during the first decade of the 21st century by the introduction and widespread administration of the conjugated heptavalent pneumococcal vaccine, which includes serotypes that most commonly express both β-lactam and macrolide resistance.[435] Studies performed in Atlanta, Georgia, before release of the vaccine, for example, documented that 31 percent of pneumococcal isolates causing invasive disease were resistant to erythromycin.[121] Follow-up studies performed after the introduction of the vaccine recorded a drop in incidence of macrolide-resistant invasive pneumococcal disease by more than two thirds.[414] As in penicillin-resistant pneumococcus, this benefit has been partially offset by an increase in the incidence of invasive diseases by macrolide-resistant organisms derived from serotypes not included in the vaccine.[101]

Similar to *S. pneumoniae*, macrolide resistance in *S. pyogenes* has been unevenly distributed geographically.[206] By the start of the 21st century, most surveys in the Western Hemisphere, including the United States,

indicated a prevalence of resistance less than 10 percent,[136,313,362,427,465] although the citywide clonal outbreak of macrolide-resistant group A streptococcus experienced in Pittsburgh, Pennsylvania, in 2001 underscored the potential for this phenotype to spread rapidly within a community.[256] Macrolide resistance in *S. pyogenes* is, on average, more prevalent in Europe, but the prevalence there also varies substantially from area to area, ranging (by 2007) from 3 percent in Norway,[240] to 13 percent in Belgium,[248] to more than 20 percent in Spain and France.[22,330] Molecular analysis of macrolide-resistant group A streptococcal isolates from geographically diverse regions suggested that the resistance genes were acquired multiple times by many lineages, some of which then disseminated worldwide.[367]

The increase in macrolide resistance has occurred concomitant with increased worldwide consumption of these compounds for respiratory tract infections beginning in the 1980s,[16,21,56,176,199,394] a finding suggesting a biologic association between these two phenomena. A nationwide survey of macrolide susceptibility among pneumococcal isolates in the United States, for example, documented an increase in erythromycin resistance from 10.6 percent in 1995 to 20.4 percent in 1999, a time when the number of prescriptions for macrolides increased by 13 percent across the board and by 320 percent in pediatric patients.[176] Seppälä and colleagues[394] reported an increase in resistance among *S. pyogenes* isolates in Finland from 5 percent in 1988 to 13 percent in 1990 after national macrolide consumption doubled during the 1980s. In response, a national campaign to reduce macrolide prescribing practices in Finland was launched in the early 1990s, after which macrolide resistance fell by half.[394] A similar campaign in Taiwan yielded similar results.[171]

Although the epidemiologic trends in macrolide resistance are alarming, the clinical consequences of the increases in macrolide resistance among streptococci are largely unknown. Current convention employs an MIC of 4 μg/mL or greater to define resistance. The newer macrolide compounds, however, achieve tissue and intracellular concentrations that are much higher than this designation.[98,304] Italian investigators, for example, noted a very high incidence of erythromycin resistance among group A streptococcal throat isolates, but neither clinical nor microbiologic failures were clearly associated with macrolide treatment.[450] The macrolides do not distribute in high concentrations to the blood compartment, however, and several reports document poor outcomes when this class of drugs is used for bacteremic pneumonia caused by macrolide-resistant pneumococcus.[210,244]

Mechanism of Resistance

Two principal resistance phenotypes to macrolides and related antibiotics have been detected. The first, denoted the *MLS_B phenotype*, is characterized by resistance to all macrolides, regardless of the size of the ring, as well as to the lincosamides and the type B streptogramins. Most organisms expressing the MLS_B phenotype remain susceptible to the combination streptogramins (e.g., quinupristin-dalfopristin).[148,388] The second phenotype, denoted the *M phenotype*, is associated with resistance to the 14- and 15-member macrolides (including erythromycin, azithromycin, and clarithromycin) but not those with 16-member rings. The degree of resistance to the affected macrolides is lower, on average, compared with that seen with MLS_B resistance. Additionally, in organisms with the M phenotype, susceptibility to clindamycin is preserved.[262,419]

Most MLS_B resistance results from methylation of the 23S ribosomal RNA (rRNA) in the 50S subunit of the bacterial ribosome within the peptidyltransferase circle in domain V.[71,187,428,466] The methylases are encoded on transposons, with sequences found both on plasmids and in the bacterial chromosome.[129] Methylation of the 23S rRNA is encoded by a family of related genes labeled *erm* (*e*rythromycin *r*esistance *m*ethylases).[71,187,428,466] Historically, these methylases have been described and named in a haphazard fashion, although some investigators have proposed renaming many of these enzymes using a classification scheme based on genetic homology.[365]

Methylation is both inducible and constitutively expressed. Unlike many other inducible antibiotic-resistance factors, the mechanism of MLS_B resistance induction is at the level of translation, rather than transcription.[464] In the uninduced state, the leader sequence of the mRNA encoding ErmC, one of the methylases found in *S. aureus*, forms two stem loop structures that stall the ribosome's movement along the message, thereby preventing synthesis of the methylase enzyme. The attachment of erythromycin to the ribosome leads to a conformational alternation of this leader sequence that uncovers the appropriate ribosomal binding sites and allows the stalled ribosomes to proceed to translation.[464] Inducible macrolide resistance is detected in the clinical microbiology laboratory by the *double-disk D-test*. In this assay, an erythromycin disk and a clindamycin disk are placed side by side on a lawn of the test organism. Induction of clindamycin resistance in the presence of erythromycin is manifested by increased growth of bacteria on the erythromycin side of the clindamycin disk, producing a "D"-shaped zone of inhibition. Through the 1990s, greater numbers of *erm*-containing bacteria produced the rRNA methylase constitutively, a consequence of mutation of the leader sequence.[84,425]

In the mid 1990s, macrolide resistance mediated through a genetically transferable efflux pump was identified.[419] Most organisms expressing the M phenotype are resistant through this mechanism. Most macrolide-resistant pneumococci in North America express the macrolide efflux pump, and much of the expansion of macrolide resistance that occurred through the 1990s was the result of the appearance of organisms exhibiting this mechanism.[176,193,238,427] A family of related genes, termed *mef*, encodes the macrolide efflux pumps. The *mef* genes are included on transposons encoding associated functions, in particular an adenosine triphosphate (ATP)–binding protein.[121,122,129,262] As expected, ribosomes isolated from organisms resistant through *mef* genes bind to macrolide antibiotics as readily as do ribosomes from susceptible organisms. Radiolabeled erythromycin is excluded from the intracellular space in *mef*-positive

bacteria, a phenomenon that is reversed by compounds that poison ATP-dependent pumps.[419]

Mechanisms of macrolide resistance besides rRNA methylation and efflux pumps have been identified but to date are uncommon. Some organisms modify the antibiotic by hydrolysis, acetylation, phosphorylation, or esterification.[365] Some evidence indicates that some erythromycin resistance is caused by altered ribosomal proteins and results in the production of ribosomes with diminished affinity for drug.[53]

Trimethoprim and Sulfamethoxazole

Clinical Relevance

The combination antibiotic TMP-SMX inhibits bacterial folate synthesis at two successive steps. This mechanism accounted for its broad activity against a wide variety of gram-positive and gram-negative bacteria when it was first introduced in 1968. Despite the dual activity of this combination, resistance to TMP-SMX has risen steadily during the decades of its use and is now commonplace. Acquisition of resistance is potentiated by recent exposure to TMP-SMX.[102,413,476] When resistance occurs, the MIC expressed usually is very high,[173,174] and the affected organisms frequently are coresistant to multiple other classes of antibiotics. Indeed, TMP-SMX resistance is sufficiently widespread that it precludes the use of the drug as a first-line antibiotic in clinical circumstances in which it was formerly the agent of choice, namely, respiratory tract infections and *Shigella*-associated dysentery. Its utility in urinary tract infection (UTI) also may be limited when the community prevalence of TMP-SMX resistance is sufficiently high. Ironically, its continued activity against CA-MRSA has rejuvenated the use of TMP-SMX among many practitioners as the incidence of infections caused by CA-MRSA organisms has mushroomed.

Respiratory Tract Infections (Otitis Media and Pneumonia). The frequency of TMP-SMX resistance in organisms causing respiratory tract infections has increased significantly. Among *S. pneumoniae* organisms, resistance to TMP-SMX was identified during the 1990s in many geographic locations, with resistance detected in 12 percent to more than 50 percent of isolates.* A worldwide survey conducted in the late 1990s noted the highest incidence of TMP-SMX pneumococcal resistance in the Asian Pacific region and in Latin America.[158] In surveys of U.S. isolates, TMP-SMX resistance is the most common resistance phenotype found in *S. pneumoniae*,[468] although the incidence of resistance varies widely from region to region.[81] TMP-SMX resistance is strongly associated with resistance to other classes of antibiotics commonly used in respiratory tract infections, particularly penicillin and the macrolides. Among other organisms implicated in respiratory tract infections, TMP-SMX resistance also has been documented with increasing frequency in *H. influenzae*, to which resistance ranges between 7 percent in Finland[253] and more than 50 percent in Taiwan.[170] The susceptibility of *M. catarrhalis* to TMP-SMX varies little from region to region. Although most *M. catarrhalis* organisms remain susceptible to TMP-SMX, the MICs cluster near achievable respiratory tract concentrations.[182]

The clinical consequences of TMP-SMX resistance in respiratory tract pathogens are not well defined. Direct evidence of the association between isolation of a TMP-SMX–resistant organism from the middle ear and failure of therapy by TMP-SMX in acute otitis media, for example, is lacking, but such an association is assumed to exist. The issue of the clinical relevance of TMP-SMX resistance in respiratory tract infections is particularly pressing in developing countries, where World Health Organization (WHO) guidelines recommend TMP-SMX as a first-line agent for pneumonia. A comparison of amoxicillin and TMP-SMX for treating pneumonia in Pakistan demonstrated superiority of amoxicillin in producing clinical cure, but treatment failure was not associated with resistance in the infecting organism.[418] These data and others[208,353,369] support the continued use of TMP-SMX therapy of pneumonia in the developing world, at least at present.

Shigellosis. Resistance of *Shigella* spp. to TMP-SMX rose dramatically during the 1980s in many parts of the world, including Bangladesh,[20] Thailand,[160] Somalia,[44] Israel,[11] and Canada.[150] In these surveys, the incidence of disease from TMP-SMX–resistant *Shigella* increased twofold to threefold, to more than half the isolates; by 1998, more than 90 percent of *Shigella* organisms in Thailand,[160] as well as *Shigella* cultured from patients with acquired immunodeficiency syndrome (AIDS) in Kenya,[222] were resistant to TMP-SMX. Many of these *Shigella* organisms express extraordinarily high levels of resistance, with MICs to TMP exceeding 1000 μg/mL. In the United States, TMP-SMX resistance among *Shigella* isolates initially was confined to closed populations.[137] A more recent survey in Oregon, however, indicated that by the late 1990s the incidence of TMP-SMX resistance among *Shigella* isolates in that state approached 60 percent. Resistant isolates were found disproportionately frequently in migrant workers traveling from Mexico and other areas of Latin America,[359] a finding emphasizing the importance of geographic spread of resistance in modern society. Subsequent surveys performed by the CDC in the early 2000s revealed that TMP-SMX–resistant *Shigella* had spread nationwide, with the prevalence highest in the East and West.[401] The incidence of TMP-SMX resistance in *Shigella* mirrors the increased TMP-SMX resistance among other enteric species as well,[137,443] notably *Salmonella*.[1,137]

TMP-SMX resistance in *Shigella* is virtually always borne on conjugative plasmids, and frequently these plasmids contain resistance determinants to several other antibiotic classes.* Coresistance to four or more unrelated antibiotics, including β-lactams, chloramphenicol, tetracycline, and the aminoglycosides, is a common finding. Molecular analyses in a given geographic environment usually indicate fluid epidemiology, with

*References 44, 137, 222, 237, 401, 443.

multiple dominant chromosomal genotypes containing a variety of resistance plasmids.[29,237]

Urinary Tract Infections. Through the 1990s and 2000s, TMP-SMX resistance in urinary tract isolates of *E. coli*, the most prominent pathogen implicated in UTIs, rose to 15 to 25 percent in the developed world and to as high as 60 percent in nonindustrialized countries.* Studies in the 1980s indicated that TMP-SMX–resistant *E. coli* can be transmitted to household contacts.[371] Indeed, one analysis suggested that TMP-SMX–resistant urinary tract isolates from geographically disparate areas of the United States may have emanated from a single clone.[251] Although urinary concentrations of both TMP and SMX are severalfold higher than concomitant concentrations in serum, resistance to TMP-SMX nonetheless is associated with treatment failure in UTIs. Bacterial and clinical response rates to TMP-SMX are 80 to 95 percent in cystitis and pyelonephritis caused by susceptible organisms, but the response falls to approximately 50 percent when the infecting agent is resistant to TMP-SMX.[266,423] Considering all urinary tract pathogens together, however, the clinical and microbiologic response to TMP-SMX is nearly equivalent to comparator agents, and experts continue to recommend this drug as the first-line therapy for uncomplicated UTIs, based on its low cost.[104,166,460] Analyses have indicated that the total expense of treatment of UTIs with TMP-SMX begins to exceed that incurred by therapy with more expensive antibiotics, such as the fluoroquinolones, when the community TMP-SMX–resistance rates of urinary pathogens exceed approximately 20 percent, as a result of the additional expense of clinical treatment failure.[229,423] Alternatives to TMP-SMX also should be considered when the patient possesses risk factors for acquisition of infection with a TMP-SMX–resistant strain, namely, recent hospitalization, diabetes, or therapy with TMP-SMX within the previous 3 months.[166]

Community-Associated Methicillin-Resistant *Staphylococcus aureus*. Despite the explosive emergence of methicillin resistance in community-associated *S. aureus* infections in the latter half of the 1990s, these organisms have remained nearly uniformly susceptible to TMP-SMX.[31,200,285] Most infections caused by CA-MRSA are skin and soft tissue infections that can be treated without hospitalization, and TMP-SMX offers an inexpensive, oral therapeutic option in this setting. The clinical effectiveness of TMP-SMX in CA-MRSA infection relative to other oral agents is uncertain; indeed, whether any antibiotic is superior to incision and drainage is not clear.[279] Experiential reports, however, support the use of TMP-SMX as a principal or adjuvant therapy for CA-MRSA cellulitis.[422]

Mechanisms of Resistance

In susceptible bacteria, TMP-SMX inhibits sequential steps in the de novo synthesis of folate (Fig. 233-3). SMX inhibits the enzyme dihydropteroate synthetase (DHPS), which catalyzes the conversion of *para*-aminobenzoic acid to dihydrofolate. TMP inhibits the next enzyme in the pathway, namely, dihydrofolate reductase (DHFR), which catalyzes the conversion of dihydrofolate to tetrahydrofolate. The resulting depletion of folate within the bacterium interrupts the synthesis of critical cellular substrates, including purine nucleotides.[368] Eukaryotic DHFR is resistant to the activity of the sulfonamides, and eukaryotic cells do not express DHPS activity at all, thus accounting for the selective activity of these drugs against bacteria.[173,174]

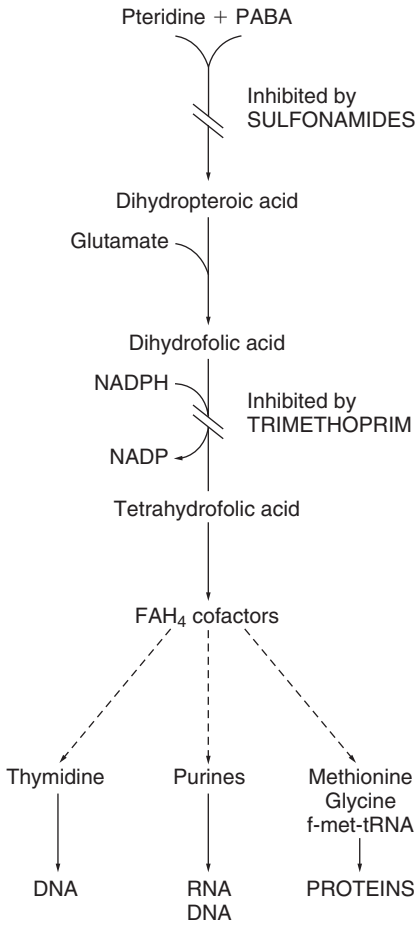

FIGURE 233-3 ■ Trimethoprim-sulfamethoxazole inhibition of de novo folate synthesis. NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate; PABA, para-aminobenzoic acid.

The principal mechanism of resistance to TMP-SMX is alteration of the target enzymes. Altered genes for DHFR with reduced susceptibility to TMP have been identified on the chromosomes of intrinsically resistant organisms from a variety of species,[339] as well as on transferable elements. Many of the transferable resistance genes are encoded on transposons that can shuttle between plasmids and chromosomal DNA. Approximately 20 different transferable *dhfr* resistance genes have been identified.[174] Resistance usually is conferred by a single-point mutation that results in a disruption of the

*References 140, 141, 205, 251, 487, 488.

three-dimensional conformation of DHFR, thereby interrupting a hydrogen bond normally available for binding the antibiotic but leaving the affinity for its natural substrate intact.[66,174,339] These structural changes may occur in concert with mutations of controlling sequences and lead to overproduction of the altered DHFR.[339] Similarly, sulfonamide resistance usually is the result of mutated *dhps* genes. In TMP-SMX–resistant *Neisseria meningitidis*, the abnormal chromosomal *dhps* sequence is different compared with that found in susceptible isolates over a large portion of the gene, a finding implying that resistance resulted from a recombination event after horizontal transfer from an unrelated *Neisseria* spp.[350] Similar recombination events may account for sulfonamide resistance in pneumococcus. In other species, the abnormal *dhps* gene is the result of a single amino acid mutation, and the resistance gene is encoded on a transmissible transposon,[312] frequently linked to a *dhfr* resistance gene.[174]

Some organisms, particularly *P. aeruginosa*, are intrinsically resistant to TMP-SMX on the basis of the expression of multidrug efflux pumps.[217] The same pumps are responsible for resistance to a wide variety of other antibiotics, including fluoroquinolones, chloramphenicol, and β-lactams. Homologous pumps occasionally have been identified in other gram-negative species as well. Finally, in some isolates, the mechanism of resistance to TMP-SMX is not attributable to any of the previously listed mechanisms and remains undefined.[174,312]

Aminoglycosides

Clinical Relevance

The aminoglycosides are parenteral antibiotics that are employed primarily for serious infections in hospitalized patients. Resistance to aminoglycosides is encoded on transmissible elements that have disseminated throughout the world, both among gram-negative and gram-positive pathogens. Among gram-negative species, resistance to the aminoglycosides varies widely according to geographic location.[387,389,447] Surveys recording longitudinal trends in susceptibility patterns of hospital-acquired isolates between the 1990s and 2000s, however, documented that, relative to other agents, the increase in resistance to the aminoglycosides has been slow, and resistance has decreased in some areas.[19,112,203] Surveys of hospital isolates conducted throughout Europe and North America in the late 1990s and early 2000s indicated resistance rates of 1 to 15 percent among enteric bacilli and 10 to 50 percent among non–lactose fermenters.* In almost all cases, the incidence of resistance was lowest to amikacin.[112,299,387,389,447] Aminoglycoside resistance occurs with much higher frequency among gram-negative organisms with coexisting resistance to other antibiotics.[14,196,286] Not surprisingly, fecal colonization with aminoglycoside-resistant bacilli is an uncommon finding among healthy persons. Although resistance to some of the older aminoglycosides, such as streptomycin and kanamycin, has disseminated into the community, carriage of organisms resistant to gentamicin is a rare finding in ambulatory populations.[234,309,348]

Few data exist recording the endemic incidence of aminoglycoside resistance in gram-negative organisms specifically among hospitalized children. In a survey of pediatric patients in an ICU in Cleveland in the mid 1990s, approximately 10 percent of patients were colonized with a tobramycin-resistant, gram-negative bacillus before discharge.[436] A survey in the neonatal ICU in the same institution, where gentamicin frequently was employed, recorded an approximate 5 percent endemic incidence of colonization with gentamicin-resistant bacilli.[433] However, outbreaks caused by gram-negative rods resistant to aminoglycoside have been reported from numerous neonatal ICUs since the early 1980s.[59,191,273]

Although the aminoglycosides have no utility in the treatment of infections with gram-positive organisms when used alone, they improve bacterial killing in vitro when they are employed in combination with cell wall–active agents. For this reason, these drugs frequently are added to β-lactam agents or vancomycin in the treatment of difficult or persistent infections caused by *S. aureus*, coagulase-negative staphylococci, or enterococci. However, resistance to aminoglycosides has been documented in all these gram-positive microorganisms. Surveys in Europe indicated 20 to 30 percent resistance to aminoglycosides among hospital isolates of *S. aureus*.[387] The occurrence of aminoglycoside resistance is much higher among MRSA isolates than in bacteria that are methicillin susceptible.[70,107] As with gram-negative bacilli, aminoglycoside resistance among *S. aureus* isolates varies greatly from region to region,[387] a finding correlating largely with the incidence of MRSA. Aminoglycoside resistance in coagulase-negative staphylococci also is a common finding. As with *S. aureus*, resistance is much more frequent among organisms that are methicillin resistant (seen in more than half of the isolates tested from centers around the world), as opposed to the unusual hospital-acquired methicillin-susceptible, coagulase-negative staphylococci, for which resistance to aminoglycosides is recorded in fewer than 10 percent.[78,215,387]

Since the 1970s, proliferation of enterococci that express MICs to the aminoglycosides exceeding 2000 μg/mL has occurred, thus rendering the organisms resistant to all synergistic effects when the aminoglycosides are used with a cell wall–active agent.[96,325] Such high-level aminoglycoside resistance has been recorded in approximately 30 percent of enterococcal samples from hospitals throughout the world.[245,286,485] Organisms expressing high-level aminoglycoside resistance frequently test highly resistant to ampicillin as well.[325] High-level aminoglycoside resistance also is a common finding in vancomycin-resistant enterococci, especially those identified in the United States.[245]

Mechanism of Resistance

The aminoglycosides are hydrophilic sugars composed of one to four rings, with amino groups substituting some

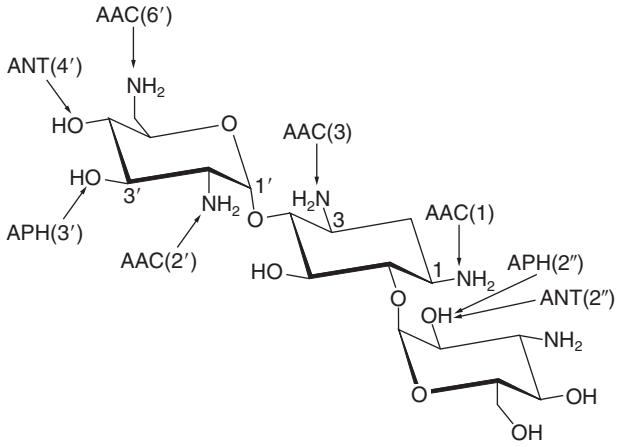
*References 107, 196, 298, 387, 389, 449.

of the hydroxyl groups at sites that vary from drug to drug. The amino groups render the drugs polycationic and allow them to bind with high affinity to selected sequences of nucleic acid.[356] The antibacterial activity of these drugs results from their binding to specific sites on the 16S ribosomal RNA that, in turn, interferes with the recognition of transfer RNA during translation and the translocation of tRNA to the peptidyl-tRNA site. Three-dimensional studies of the aminoglycoside-rRNA interaction suggest that this interference is the result of conformational changes in the shape of the rRNA.[221] The affinity of the aminoglycosides to ribosomal RNA is 10-fold higher in prokaryotes than in eukaryotes.[355]

The principal mechanism of resistance to the aminoglycosides is through the expression of aminoglycoside-modifying enzymes (Table 233-3). Many of these enzymes are encoded on transposons that reside in plasmids along with other resistance determinates. Three groups of modifying enzymes have been identified, namely, acetyltransferases (AAC), nucleotidyltransferases (ANT), and phosphotransferases (APH), each of which adds its respective moieties to selected side groups of the aminoglycoside sugar rings.[221,396] Researchers have hypothesized that these genes originated from bacterial housekeeping enzymes and then expanded to include aminoglycosides among their substrates through mutational evolution.[396] Transcription of these resistance genes is constitutive. Most members of each group of modifying enzymes share structural homologies, with minor amino acid variations resulting in specific substrate profiles.[396] The enzymes are subdesignated by the site they modify and by the resistance profile they confer (Fig. 233-4). Thus, for example, AAC(6′)-II denotes an AAC that substitutes an acetyl group for the amino group at the 6′-site of the aminoglycoside, with a resulting resistance pattern II (including, in this case, resistance to gentamicin, tobramycin, and sisomicin, but not amikacin). At least one enzyme has been discovered that possesses both AAC and APH activity [designated AAC[6′]-Ie-APH[2″]-Ia].[54,215,396,485] The modifications conferred by these enzymes result in altered electrostatic qualities of the antibiotic and consequent reduced ability to interact with rRNA.

The pharmaceutical industry has altered the structure of the aminoglycoside compounds to render them poorer substrates for the modifying enzymes. This exercise has been most successful in the development of amikacin, a kanamycin derivative with a relatively long amino hydroxybutyrate added at the 1 position.[280] This substitution does not interfere with rRNA binding but protects the compound from alteration by many of the modifying enzymes. Consequently, organisms resistant to gentamicin, for example, may remain susceptible to amikacin. Not all positions are protected, however, and amikacin-resistant phenotypes are conferred by certain modifying enzymes, most notably AAC(6′)-I.[280]

Moderate-level resistance to the aminoglycosides has been achieved by some bacteria through decreased uptake of drug.[280] This mechanism has been noted most frequently in *Pseudomonas*. To date, modifications of the ribosomal binding sequences have been identified only rarely as a mechanism of resistance to the aminoglycosides.[280] The sequences involved in aminoglycoside binding likely are sufficiently critical to the survival of the organism that mutations within this site usually are fatal.[221]



Kanamycin B

Glycopeptides and Other Antibiotics Directed Against Gram-Positive Bacteria

Clinical Relevance

Vancomycin is one of two glycopeptides available for clinical use. The second, teicoplanin, is licensed in Europe but not the United States. Since the late 1980s, the prevalence of vancomycin resistance in organisms belonging to the genus *Enterococcus* (vancomycin-resistant enterococci [VRE]) has risen alarmingly. VRE frequently are highly resistant to many other antibiotics as well, and reported mortality from infection caused by these resistant organisms exceeds 30 percent.[76,287,399]

The appearance of VRE occurred coincident with an increased use of vancomycin in the United States and the use of the glycopeptide avoparcin as a growth promoter in animal feed in Europe, a practice banned by the European Union in 1997.[291] The incidence of VRE colonization and disease is much more prevalent in the United States than in other areas of the world,[77,245] but these organisms are present globally.[169,469] Ten to 20 percent of U.S. enterococcal isolates investigated in surveys in the late 1990s and early 2000s were resistant to vancomycin.[77,245] A disproportionate number of VRE in the United States are found in patients hospitalized in ICUs in large urban medical centers, especially among persons with prolonged hospitalizations and severe disease.[152,245,246,399] Additionally, a high incidence of VRE is seen among oncology patients,[95,260] transplant recipients,[94,275] and those with chronic renal failure who are receiving dialysis.[12,105,454] Some surveys have documented VRE among adults in chronic care facilities, who exported the organism into the community after acquisition in an acute care setting.[438] By contrast, the prevalence of VRE is relatively low in U.S. hospitals serving rural areas.[343,416]

Surveys of European centers also indicate a concentration of VRE in ICUs but in smaller numbers compared with the United States.[376,390] The occurrence of VRE in Europe, however, varies widely from country to country. In 2010, the proportion of blood isolates of *E. faecium* that were resistant to vancomycin ranged from 0 percent in Sweden and Finland to over 20 percent in Portugal, Greece, and Ireland.[45] VRE also have been reported in Asia and Latin America but at rates approximately half those found in the United States.[45]

The genetic machinery conferring vancomycin resistance in enterococci is complex, and resistance does not develop de novo by spontaneous mutation under antibiotic pressure.[291] The initial event in the appearance of VRE in a given unit is the importation of the resistant organism into the environment. The association between antecedent treatment with vancomycin and acquisition of VRE has been documented by many,[111,399] but not all, investigators.[42,86] Some researchers have established a stronger connection between the appearance of VRE and the use of extended-spectrum cephalosporins[26,311] and antibiotics with potent antianaerobic activity.[246] A study conducted in a Veteran's Affairs hospital reported that the stool density of VRE in patients who were treated with antianaerobic antibiotics increased exponentially, whereas the density decreased in those whose antibiotics had limited anaerobic activity.[85] The principal role of antecedent antibiotic exposure in VRE may be to open up ecologic niches in the gastrointestinal tract that allow a stable presence of VRE once the patient is exposed to the resistant organism.

Horizontal transmission of VRE is prominent in any closed environment and may outweigh antecedent antibiotic exposure as the principal determinant for acquisition.[26,152] Patient-to-patient spread in an ICU, presumably through the hands of caregivers, has been documented repeatedly, as has contamination of the immediate environment of the VRE-positive patient.[311,403] Indeed, perhaps the most significant risk factor for acquisition of VRE is the number of neighboring patients colonized with the organism at the same time.[13,26,65]

In many U.S. ICUs, multiple clones of VRE are present at any given moment, some imported into the unit and others spread after admission has occurred,[311] thus rendering control and containment very difficult to achieve. Extreme barrier isolation precautions, including surveillance for VRE on admission to a given unit, single-room isolation with dedicated medical instruments, and strict use of gowns and gloves, frequently are necessary to contain VRE once it has established an endemic presence, and even then these measures may not be entirely effective.[190,225,403]

With some exceptions,[134,274,440] to date VRE have been less a threat to pediatric patients than to adults, despite the wide use of vancomycin among hospitalized pediatric patients and their geographic proximity in many hospitals to sick adults colonized with the organism. Several outbreaks of VRE in the newborn nursery have been reported,[233,249] but they have resulted primarily from dissemination of a single clone within the unit and have been successfully eradicated with implementation of relatively simple barrier isolation and cohorting measures.

In the latter half of the 1990s, a second phenomenon involving reduced susceptibility to vancomycin was identified, namely, vancomycin-intermediate *S. aureus* (VISA).[110,405] These organisms express MICs to vancomycin in the intermediate range of approximately 8 μg/mL. Virtually all such isolates are coresistant to methicillin, but several have retained susceptibility to numerous other antimicrobial agents. To date, VISA isolates have been identified primarily in patients who have been treated with prolonged courses of vancomycin for MRSA infection. Disproportionate numbers of these patients have been undergoing dialysis.[406] Eradication of VISA has been difficult but achievable with high doses of vancomycin in combination with other antibiotics.[110,406] At present, infection with VISA is a rare occurrence, both in adults and in children.

In 2002, the first two cases of true vancomycin-resistant *S. aureus* (VRSA) in the United States were reported, one from Michigan and the other from Pennsylvania (MIC to vancomycin >128 μg/mL and =32 μg/mL, respectively).[444,445] Both patients were suffering from chronic foot ulcers from which the organisms were isolated. In both instances, the bacteria were susceptible to alternative agents, and the patients remained clinically stable. The potential for VRSA to emerge as a

major public health hazard is substantial, but subsequent cases have been rare.[446]

Mechanisms of Resistance

By 2012, eight genotypes for vancomycin resistance in enterococci had been defined, labeled VanA through VanE and VanG, VanL, VanM, and VanN, each associated with phenotypic nuances.[62,291] These genotypes differ in the species of enterococci affected, the relative resistance conferred to vancomycin and teicoplanin, and whether they are inducible or constitutively expressed (Table 233-4). The VanC phenotype is distinct from the others in that it is an intrinsically expressed, species-specific product of *Enterococcus gallinarum*, *Enterococcus casseliflavus*, and *Enterococcus flavescens.*[294] The other vancomycin genotypes are acquired, although several are not readily transferable (see Table 233-4). The marked majority of human isolates are derived from the VanA group.

In susceptible bacteria, the glycopeptides are large molecules that interfere with cell wall peptidoglycan synthesis at a point proximal to that targeted by the β-lactam antibiotics. Specifically, the synthesis of peptidoglycan in vancomycin-susceptible bacteria includes the incorporation of a D-alanyl-D-alanine dipeptide onto the carboxyl end of the growing glycopeptide chain to form a pentapeptide precursor. The pentapeptide is translocated from the cytoplasm to the outer surface of the bacteria.[62] The D-Ala-D-Ala carboxy-terminal end of the pentapeptide is critical for the continued synthesis of the peptidoglycan chain and, ultimately, for peptidoglycan cross linking and the formation of a stable cell wall. Vancomycin, which never enters the cell, binds to the D-Ala-D-Ala moiety of the pentapeptide through several hydrogen bonds along the outer surface of the cell wall,[17] thereby blocking synthesis of the remaining macromolecule.

The molecular basis for vancomycin resistance results from the complex, coordinated interactions of multiple genes usually encoded on a single genetic element. These interactions have been defined best for the VanA phenotype, although genetic homologues are found in organisms expressing the other vancomycin-resistant phenotypes. The genetic machinery for VanA resides on the 10,851-bp transposon Tn*1546.*[8,456] The molecules central to conferring the resistant phenotype are encoded by the contiguous genes labeled *vanH*, *vanA*, and *vanX*, all of which are essential for expression of vancomycin resistance. The *vanA* gene encodes a ligase that, unlike the native enterococcal ligase, produces an abnormal D-alanyl-D-lactate dimer over the normal D-alanyl-D-alanine.[34] This process results in the formation of the peptidoglycan precursor uridine diphosphate–MurNAc–L-Ala-D-Glu-L-Lys-D-Ala-D-Lac, the carboxy terminus of which has profoundly reduced affinity for vancomycin.[35,45] The homologous ligase in VanC-, VanE-, and VanG–expressing organisms synthesizes D-Ala-D-Ser (see Table 233-4) with similar consequences,[62,291] although the degree of resistance conferred by formation of D-Ala-D-Ser is less profound than that conferred by D -Ala-D-Lac. VanH catalyzes the reaction taking pyruvate to D-Lac and increases the availability of this substrate to VanA for production of the D-Ala-D-Lac dimer.[35] *vanX* and a second gene labeled *vanY* encode a cleaving enzyme for the D-Ala-D-Ala dipeptide, thus reducing the natural cellular substrate for the D-Ala-D-Ala adding enzyme and resulting in greater relative incorporation of D-Ala-D-Lac into the peptidoglycan precursor.[62,360]

The *vanS* and *vanR* genes included on the same vancomycin-resistance transposon regulate expression of resistance. The products of these genes are homologous to other compounds of so-called two-component regulatory systems.[442] Ultimately, the result is transcription of the resistance genes in the presence of vancomycin.[62] The functions of the last two gene products, VanY and VanZ, are not essential for expression of the resistant phenotype.[9,10]

TABLE 233-4 Types of Resistance to Glycopeptides in Enterococci

	Acquired Resistance								Intrinsic Resistance
	High Level		Variable	Moderate	Low Level				Low Level

From Cattoir V, Leclercq R. Twenty-five years of shared life with vancomycin-resistant enterococci: is it time to divorce? J Antimicrob Chemother 2012 Dec 2. [Epub ahead of print].

Between 2002 and 2012, 12 adult patients were described who had fully vancomycin-resistant MRSA infections from *S. aureus* harboring the TN*1546* transposon found in VRE.[9,10,45,444-446] This finding indicated that true VRSA could result from the conjugal transfer of the vancomycin-resistance transposon from VRE to MRSA, a phenomenon that can be replicated in vitro.[301] By contrast, VISA isolates do not contain the resistance genes found in VRE; rather, these isolates acquire unusual extracellular material around the cell wall as detected by electron microscopy.[36,406] This layer represents accumulated peptidoglycan with reduced levels of cross linking, thereby exposing an excess of D-Ala-D-Ala moieties that bind to vancomycin before it can reach the cell wall.[457] Other vancomycin-resistance phenomena in *S. aureus* have been described and include those in which subpopulations express MICs twofold to eightfold higher than those in the parent population (termed *heteroresistance*),[110,198] as well as those in which *S. aureus* can be inhibited but not readily killed by vancomycin (termed *tolerance*).[263] Some investigations indicated that isolates of *S. aureus* expressing vancomycin heteroresistance develop into VISA with continued exposure to the drug.[457]

Resistance to Other Antibiotics Used for Gram-Positive Bacterial Infections. Two antibiotics introduced in the early 2000s, namely, linezolid and daptomycin, were developed to address the increasingly important problem of antibiotic-resistant, gram-positive pathogens, especially VRE and MRSA. In both instances, the antibiotic represented a novel class of molecules, in the hope that resistance would be slow to develop.

Linezolid, the first of the oxazolidinone antibiotics, has activity against all important human gram-positive pathogens, including MRSA, VISA, coagulase-negative staphylococci, and VRE. Gram-negative organisms are intrinsically resistant to linezolid, because they express efflux pumps that extrude the drug from the cytoplasm.[243] The molecular target of the oxazolidinones is domain V of the 23S rRNA of the 50S bacterial ribosomal subunit. Binding to this domain results in the inhibition of the initial steps of translation.[421] Although there is some overlap with the binding sites of other antibiotics whose activity is directed against the ribosome,[243] linezolid's binding site is unique to the oxazolidinones. Because the oxazolidinones are entirely synthetic, likely no significant natural resistance to this class of drugs existed before the introduction of linezolid.[277] To date, resistance to linezolid in vivo has been a rare occurrence. Multinational surveys conducted throughout the first decade of the 2000s have identified remarkably few linezolid-resistant organisms, despite the widespread use of the agent.[73,194,299] In most surveys, over 99 percent of *S. aureus* (including MRSA) and enterococci (including VRE), and more than 98 percent of coagulase-negative staphylococci, remain linezolid susceptible.[138,243,439,492] The few linezolid-resistant clinical isolates that have been encountered have been derived from enterococci, *S. aureus* and coagulase-negative staphylococci, usually after prolonged exposure to drug.[27,138,303,470] Three principal mechanisms of linezolid resistance have been defined. The majority of linezolid-resistant organisms possess a mutation in the gene encoding domain V of the 23S rRNA.[243,277] Most bacteria have multiple copy numbers of this gene. The degree of resistance is gene dose dependent, such that the MIC of linezolid usually remains in the susceptible range after a single mutation occurs but increases incrementally as each allele is affected.[277] In other linezolid-resistant organisms, the resistant phenotype is conferred through mutations of the ribosomal proteins L3 and L4.[243] Finally, ribosomal binding of linezolid may be inhibited by methylation of the rRNA; this mechanism is mediated through the plasmid-borne enzyme Cfr methylase.[243] Such methylation results in cross resistance to clindamycin and the streptogramin A antibiotics.[243] In some instances, Cfr-bearing plasmids include several other antibiotic resistance determinants as well.[133]

Daptomycin, a fermentation product of *Streptomyces roseoporus*, is a unique antimicrobial with activity against a full range of gram-positive bacteria. The compound is a cationic cyclic lipopeptide that interacts with the cell membrane in a manner similar to related cationic peptides that constitute part of the natural human host defense mechanisms against microbes. In the presence of calcium, this event disrupts the transmembrane electrical potential with a secondary interruption of ATP and macromolecular synthesis.[148,412] As with linezolid, laboratory surveys of large numbers of gram-positive clinical isolates from many areas of the world indicate that daptomycin resistance is rare.[373-375,439] Soon after daptomycin was introduced in the early 2000s, however, several cases were reported documenting the emergence of *S. aureus* and enterococci with reduced susceptibility to daptomycin during prolonged therapy.* In these cases, the infection emanated from a bony or endovascular focus into which penetration of the drug may have been limited. Daptomycin resistance has been linked to mutations in multiple genes that regulate the composition and integrity of the bacterial cell membrane.[114] The mutations implicated in daptomycin resistance differ in *S. aureus* and enterococcus, but in sum they result in alterations in the phospholipid content of the bacterial cell surface, changing its charge and thereby decreasing the affinity of the drug to its target.[7,209,282,370,437] Ultrastructural analysis of daptomycin-resistant isolates reveals a thickened envelope, and several reports have correlated vancomycin-intermediate resistance in *S. aureus* and reduced susceptibility to daptomycin.[7,64,448]

The cephalosporin ceftaroline was introduced into clinical practice in the latter part of the 2000s. In distinction to all prior cephalosporins, ceftaroline exhibits a high affinity for the penicillin-binding protein PBP2a responsible for conferring methicillin resistance in staphylococci,[382] rendering the drug active against MRSA. Additionally, it has activity against multidrug-resistant pneumococci as well as against staphylococci with intermediate resistance to vancomycin and reduced susceptibility to linezolid and daptomycin.[382] Its activity against enterococcus is variable.[382] Several surveys testing ceftaroline against a wide range of staphylococcal and pneumococcal clinical isolates in the late 2000s confirmed its

*References 7, 153, 209, 252, 258, 282.

nearly uniform in vitro activity.[99,100,106] Even early in ceftaroline's clinical history, however, a ceftaroline-resistant strain of MRSA was isolated and expressed a PBP2a molecule with reduced affinity to the drug.[278]

Quinolones

Clinical Relevance

The quinolone family of antibiotics possesses activity against a broad variety of microorganisms. As of the early 21st century, the quinolones had not been labeled for pediatric use. However, the safety profile in children of the more recently developed quinolones (i.e., the fluoroquinolones) is similar to that recorded in adults[123,189,384] and this class of antibiotics has been effectively employed in selected children with serious infections caused by bacteria resistant to alternative agents. The following subsections discuss clinical circumstances in which quinolone resistance is relevant to pediatric practice.

Cystic Fibrosis. The lungs of patients with cystic fibrosis (CF) are chronically infected early in life, primarily with *S. aureus* and later with *P. aeruginosa*. Exacerbations of pulmonary symptoms are treated effectively with antibiotics directed against these microorganisms. Ciprofloxacin represents the first oral agent with significant anti-*Pseudomonas* activity and manifests potency generally superior to that of the other fluoroquinolones.[337] As a result, experts in many centers treat patients with CF with ciprofloxacin, even when the recipients are younger than 18 years of age.[123] In most circumstances, pediatric patients with CF treated with ciprofloxacin have experienced improvement in their respiratory status.[385]

Pseudomonas surveys conducted with organisms derived from patients with CF as well as those without CF indicated susceptibility to ciprofloxacin in 50 to 90 percent of strains; CF isolates tended to express resistance more frequently than did other isolates.* Several investigators documented that decreased susceptibility of *Pseudomonas* lung isolates to ciprofloxacin occurs frequently during the course of ciprofloxacin treatment in patients with CF.[87,411] Indeed, high proportions of *Pseudomonas* strains infecting the lungs of patients with CF are "hypermutators," particularly prone to spontaneous mutation resulting from defects in genetic repair mechanisms,[308] that allow the ready emergence of antibiotic resistance. However, as a general rule, patients who improve clinically during therapy for an acute pulmonary exacerbation do not eradicate the infecting organisms, and the importance of emergence of resistant bacteria during therapy versus any of the commonly employed antibiotics is uncertain, as long as the infecting organisms were susceptible initially.[404] Moreover, frequently the *Pseudomonas* reverts back to a quinolone-susceptible phenotype several weeks after treatment with ciprofloxacin has been completed.[80,87] As a result, ciprofloxacin currently appears to be a useful option for patients with CF who have worsening pulmonary disease, if at least one of the organisms in the initial sputum culture is susceptible.

The usefulness of ciprofloxacin in the patient with CF who is infected with *S. aureus* also probably depends on the susceptibility of the pretreatment isolates. A worldwide survey conducted in the late 1990s indicated that most methicillin-susceptible strains of *S. aureus* also were susceptible to ciprofloxacin and other fluoroquinolones. However, the fluoroquinolone susceptibility among methicillin-resistant strains was less than 20 percent and susceptibility was extraordinarily low to ciprofloxacin in particular.[109,139,163]

Enteric Gram-Negative Bacilli: Uropathogens, Nosocomial Bacteria, and Agents of Bacterial Enteritis

Quinolone resistance in enteric gram-negative rods, particularly among uropathogens, has been an uncommon occurrence in North America. Studies of enteric urinary tract isolates in the United States and Canada documented susceptibility rates to ciprofloxacin of 95 percent or greater during the 1990s and 2000s among nonelderly patients,[487] a finding supporting the effectiveness of quinolones for community-acquired cystitis and uncomplicated pyelonephritis.* In contrast, in some regions of Europe, the incidence of quinolone resistance among uropathogens has increased as administration of this class of antibiotics has become more widespread.[118,131,168] A 1998 survey of urinary tract isolates from Latin America indicated an even more dramatic occurrence of quinolone resistance: 22 percent of *E. coli*, 30 percent of *P. mirabilis*, and more than 35 percent of *Enterobacter* were ciprofloxacin resistant.[118] Quinolone resistance in gram-negative urinary pathogens frequently is associated with resistance to other classes of antibiotics as well.[204] Consequently, several experts continue to recommend TMP-SMX over the fluoroquinolones as the first-line agent for uncomplicated UTIs, because clinical and microbiologic efficacy is nearly equivalent for the two classes of drugs and routine use of quinolone will needlessly promote quinolone resistance.[104,166,460]

The quinolones traditionally have been mainstays of treatment for nosocomial infections in adult patients with severe illness. During the late 1990s and early 2000s, however, quinolone resistance in nosocomial gram-negative pathogens increased in many areas of the world among both Enterobacteriaceae and non–lactose fermenters.[112,196,203,286,299] In several instances, quinolone resistance in gram-negative bacilli increased more rapidly than any other resistance phenotype.[112,196] Many of these hospital-acquired pathogens coexpress ESBLs and other resistance determinants.[6,32,324]

Antibiotic therapy, including treatment with quinolones, for bacterial enteritis usually is not indicated.[472] That said, with the exception of *Campylobacter*, most agents that cause bacterial enteritis have remained susceptible to the quinolones by in vitro testing,[130] although epidemic strains of both *Shigella* and *Salmonella*

*References 43, 109, 132, 155, 254, 379, 398.

*References 91, 104, 140, 141, 229, 266, 423.

expressing quinolone resistance have been identified in Asia.[116,327,424] *Salmonella typhimurium* DT104, which spread rapidly throughout Europe and the United States in the late 1990s, is resistant to nalidixic acid, but most isolates (except for some identified in the United Kingdom) are susceptible to the newer fluoroquinolones.[115,130,154,283] Similarly, surveys of other non-*typhi Salmonella* conducted in the early 2000s indicated that few were ciprofloxacin-resistant, although as many as one fifth of the strains had reduced susceptibility to the drug.[143,255,415]

In contrast to resistance among other enteritis-associated bacteria, quinolone resistance among *Campylobacter* isolates from many parts of the world has become prominent and high level.[160,186,335,475] *Campylobacter* can acquire quinolone resistance shortly after exposure to the antibiotic. Indeed, clinical relapse with quinolone-resistant organisms after therapy for *Campylobacter* enteritis is relatively common.[335,475] The introduction of quinolones into poultry feed for animals bred for food has exacerbated the spread of *Campylobacter* resistance in humans.[297,405] In chickens obtained from several different supermarkets in Minnesota in the mid 1990s, nearly 90 percent of samples were culture positive for *Campylobacter*; and approximately 20 percent of these samples were resistant to ciprofloxacin.[405] These circumstances prompted a U.S. Food and Drug Administration ruling withdrawing the use of quinolone in poultry in 2005. It is likely, however, that quinolone-resistant *Campylobacter* has found a stable ecologic niche in both animals and humans and will continue to be encountered despite this intervention.[297] Unlike most other bacteria, *Campylobacter* becomes highly resistant to the quinolones after a single mutation,[128,459] so most quinolone-resistant clinical isolates demonstrate MICs of 32 μg/mL or more, much higher than the conventional cutoff for defining quinolone resistance.

Community-Acquired Respiratory Tract Infections. The applicability of quinolones to respiratory tract infections has been shadowed by the marginal activity of the first modern quinolones, namely, ciprofloxacin, ofloxacin, and norfloxacin, against *S. pneumoniae*. MICs of these antibiotics against most clinical isolates of *S. pneumoniae* average 1 to 2 μg/mL, concentrations that are close to those achievable in bronchial secretions.[337] Several reports of clinical treatment failures were reported in which ciprofloxacin was administered in pneumococcal disease in the respiratory tract.[218,231,329] Moreover, even when *S. pneumoniae* was not the intended target of therapy, the wide use of the early quinolone agents in treating community-acquired infections during the 1990s resulted in the inadvertent exposure of respiratory tract colonizers, including *S. pneumoniae*, to these agents; the result was an even greater, albeit gradual, increase in the MICs of community-acquired *S. pneumoniae* isolates to ciprofloxacin.[48,103,192,378] By the mid 2000s, surveys recorded a prevalence of ciprofloxacin resistance (MIC ≥4 μg/mL) in *S. pneumoniae* of approximately 2.5 percent in the United States,[83,363] 4 percent in Canada,[2] and 15 percent in Italy.[74]

Most of the more recently introduced fluoroquinolones are substantially more potent against *S. pneumoniae* than is ciprofloxacin[220] and express MICs that are easily achieved in the respiratory tract. Usually, susceptibility is maintained, even in isolates resistant to the older quinolone agents.[195,337,364] However, MICs against the newer quinolones roughly correlate with those expressed against ciprofloxacin.[48,192,195,364] Consequently, clinically relevant resistance also has begun to emerge against these newer agents, particularly levofloxacin.[2,74,341,363] To date, susceptibility of other respiratory tract pathogens, including *H. influenzae*, *M. catarrhalis*,[23,181,337] and the bacterial agents causing atypical pneumonias, remains very good to all the fluoroquinolones, although exceptions, particularly in *Haemophilus* spp.,[295,483] have been reported.

Mechanisms of Resistance

The two principal molecular targets of the quinolone antibiotics are the topoisomerases DNA gyrase and topoisomerase IV. These enzymes mediate the three-dimensional topologic configuration of the bacterial duplex DNA ring during cell division and transcription and allow the repair and replication of nucleic acid and the separation of daughter chromosomes in the cramped intracellular environment to occur.[151,164] Several reactions have been identified that are mediated by these two bacterial DNA topoisomerases, including negative supercoiling and catenation.[161,420] Both DNA gyrase and topoisomerase IV are composed of two nonidentical subunits. In DNA gyrase, these subunits are labeled GyrA and GyrB, which are constructed into an A_2B_2 tetramer.[161,420] Quinolones bind to the GyrA subunit of the DNA gyrase-DNA-ATP complex and prevent further progress of the enzyme along the nucleic acid.[161] Bacterial cell death is enhanced by the release of toxic DNA ends from the quinolone-gyrase DNA complex.[151] Topoisomerase IV is composed of two equivalent subunits, labeled ParC and ParE, which share sequence homologies to GyrA and B, respectively.[162]

Quinolone resistance is conferred through several molecular mechanisms. Most organisms resistant to the fluoroquinolones demonstrate one or more mutations in DNA gyrase, topoisomerase IV, or both. Resistance to quinolones among gram-negative bacilli usually is mediated through mutations in DNA gyrase, whereas resistance in gram-positive organisms is the result of alterations of topoisomerase IV.[151,316,493] However, this pattern varies from organism to organism (e.g., the primary target in *S. pneumoniae* appears to be DNA gyrase) and from quinolone to quinolone.[151,162] In gram-negative bacilli, most first-step resistance-conferring mutations occur in *gyrA*, the gene encoding the GyrA subunit. These mutations are clustered in a segment termed the *quinolone-resistance determining region* (QRDR).[336,381,481,482] Hybrid DNA gyrase molecules composed of the A subunit from a resistant bacterial strain and the B subunit from a susceptible isolate confer quinolone resistance.[40] Within the QRDR, most mutations have involved the substitution of a serine for a bulkier, nonpolar amino acid at a single, specific site. This mutation, first identified in *E. coli*,[452,481] has been documented since in a variety of organisms.[69,179,219,284,351] Other amino acid substitutions near this site also have been described, with multiple-site mutations resulting in

increased quinolone resistance compared with a single mutation alone.[452] Mutations of the GyrB subunit, which result in a quinolone-resistant phenotype, also have been identified. In general, mutations affecting the GyrB subunit result in lower levels of resistance than those noted with GyrA.[482] As with GyrA mutations, those affecting GyrB preferentially localize to specific amino acids.[482]

In most quinolone-resistant, gram-positive organisms, mutations of topoisomerase IV occur at locations that are the equivalent to those noted in DNA gyrase. First-step mutations most frequently are noted in *parC*, which, like *gyrA*, contains a hot-spot segment around which most resistance-conferring mutations occur.[161,162,336] *GyrA* mutations in these organisms frequently are clinically silent unless they occur concomitantly with a mutation in *parC*.[161]

Three additional mechanisms of quinolone resistance, which may appear together and in conjunction with a topoisomerase mutation in the same cell, have been identified. Two of these additional mechanisms result in diminished intracellular accumulation of drug. The first mechanism involves decreased entry of antibiotic into the cell secondary to alterations in porin composition, a mutation that generally results in only moderate drug resistance and that affects individual quinolones differentially, depending on their hydrophilicity.[381] Particular attention has centered on alterations in outer member protein F (OmpF).[165,489] This mutation, identified principally in *E. coli*, frequently is associated with resistance to other classes of antibiotics as well, including chloramphenicol, tetracycline, and some of the β-lactams. The diminished expression of OmpF in these resistant isolates does not appear to result from mutations in the corresponding structural gene or its regulatory sequences. Rather, the decreased expression of this outer-membrane protein is mediated through the enhanced expression of the gene *micF*, which transcribes an antisense RNA complementary to the 5′ end of the *ompF* message,[5] thereby destabilizing its binding to the ribosome. Occasional mutants involving additional strains of Enterobacteriaceae have demonstrated other alterations in outer-membrane porin composition.[40]

In the second mechanism, many quinolone-resistant species mediate their resistance through increased drug efflux.[235,236,257] Both bacterial and eukaryotic cells normally encode several efflux pumps that provide protection from a range of potential exogenous toxins.[326] The overexpression of an efflux pump resulting from the mutation of a controlling sequence accounts for reduced susceptibility to quinolones in many clinical isolates.[183,257] Individual efflux pumps select substrates based on their physical chemical properties (e.g., hydrophobicity and net charge), rather than their gross structural similarities; therefore, the various quinolone compounds, which differ from one another regarding these properties, may be differentially susceptible to organisms expressing these pumps.[326]

The gene encoding the quinolone efflux pump in *S. aureus*, labeled *norA*,[480] has been cloned and sequenced. Transformation of susceptible bacteria with the putative gene results in a resistant phenotype, for which resistance can be abolished by the addition of inhibitors of energy-dependent cellular pumps.[480] This pump, however, appears to be able to transport only hydrophilic quinolones; intracellular accumulation of the hydrophobic drug sparfloxacin, for example, is unaffected.

A range of additional genes encoding efflux pumps capable of producing quinolone resistance has been identified in other species, such as *prmA* in *S. pneumoniae*,[336] *acrAB* in *E. coli*,[183,250] and the *mexAmexB-oprM* complex in *P. aeruginosa*.[259] This third complex gene encodes components that transport the drug through both the cell wall and across the periplasmic space, as well as an outer-membrane protein.[326] Most of these pumps are able to extrude a wide variety of exogenous substances, such as detergents, dyes, and other antibiotics, from the bacterial cytoplasm.[183] Therefore, reduced susceptibility to quinolones may be selected by exposures unrelated to the quinolones themselves.

The first decade of the 2000s has witnessed the rapid emergence of transmissible plasmid-mediated quinolone resistance, the third mechanism. All previously defined mechanisms of quinolone resistance were chromosomal. Organisms exhibiting the transmissible mechanism have been identified in Asia, Europe, and North America.[366] The products encoded by these plasmids have been labeled *Qnr proteins*, a group of molecules that bind to topoisomerase and protect it from the inhibitory effects of the quinolones.[302,366] Although all the Qnr molecules described to date belong to the so-called pentapeptide-repeat family of proteins, a finding suggesting similar three-dimensional conformations, distinct families of Qnr proteins with largely nonhomologous amino acid sequences have been characterized.[302,366] These families have been named QnrA, QnrB, and QnrS, with subtypes identified within each. The variety of plasmid and integron structures carrying Qnr proteins and the multiplicity of sequences of the proteins themselves support the notion that Qnr-mediated resistance arose through many independent molecular events in geographically distinct regions of the world. The plasmids encoding the Qnr proteins have been found in multiple species belonging to the Enterobacteriaceae, but to date they have not been identified in nonenteric bacteria such as *Pseudomonas* and *Acinetobacter*.[366] Qnr plasmids frequently carry other antibiotic-resistance genes, most notable those encoding ESBLs and the aminoglycoside-modifying gene *aac(6′)-Ib-cr*, a gene that is able to acetylate selected quinolones as well.[366] The plasmids also may carry resistance determinants against rifampin, tetracycline, sulfonamides, and chloramphenicol.[302]

Quinolone resistance occurs incrementally as the organism acquires a series of topoisomerase mutations, altered outer-membrane proteins, overexpressed efflux pumps, and Qnr proteins.[97] Thus, in gram-negative species, mutations of *gyrA* usually occur in first-step mutants producing relatively small increases in the MIC and frequently result in bacteria that still are susceptible to the antibiotic. Additional mutations to *gyrA*, or added mutations to *parC* or the overexpression of an efflux pump, which may in themselves confer undetectable or only minor resistance to the quinolones, result in substantial quinolone resistance when they operate in

concert.[162,381] Therefore, choosing a fluoroquinolone that can achieve a sustained concentration at the site of infection severalfold higher than the MIC may suppress the emergence of resistance, because this concentration is sufficient to suppress growth of both the parent organism and first-step mutants.[92,381] The propensity of a bacterial strain to emerge resistant to the quinolones can be quantified empirically by measuring the *mutant prevention concentration* (MPC), that is, the lowest concentration of quinolone required to suppress the emergence of resistant subpopulations among a high inoculum (10^{10}) of bacteria.[92,151] The acquisition of each resistance determinant results in an increase in MPC disproportionate to the increase in MIC, a finding indicating that ever-increasing concentrations of drug are required to halt the escalation of resistance as new resistance mechanisms are gained.[151,183]

Chloramphenicol

Clinical Relevance

In industrialized nations, chloramphenicol has been supplanted by other agents with similar or improved antibacterial potency and less toxicity. However, the antibiotic remains a staple for pediatric bacteremia and meningitis in the developing world because of its broad antibacterial activity, low cost, favorable achievable serum concentrations after oral or intramuscular administration, and excellent penetration across the blood-brain barrier. The incidence of resistance to chloramphenicol among the principal organisms causing bacteremia and meningitis in children, namely, *H. influenzae*, *S. pneumoniae*, *N. meningitidis*, and *Salmonella*, varies greatly by geographic location. Between the late 1980s and the early 2000s, surveys of *H. influenzae*, both type b and non–type b, were completed in several areas of the world. In vitro resistance to chloramphenicol ranged between 0 percent of isolates (from the Central African Republic and various locations in South America) and more than 50 percent (in India and Kenya).* Studies in 2001 and 2003 of *H. influenzae* isolates in Canada and the United States, where infection by these organisms is almost always treated with an alternative agent, indicated chloramphenicol resistance in fewer than 0.5 percent of tested bacteria.[158,490]

International surveys completed in the mid to late 1990s that measured in vitro susceptibility of *S. pneumoniae* to chloramphenicol indicated resistance exceeding 10 to 20 percent in many areas of the world.[182,232,310,369] Chloramphenicol resistance was recorded in approximately 10 percent of European isolates of *S. pneumoniae* and in 5 percent of isolates identified in the United States and Canada.[158] Resistance to chloramphenicol is seen more commonly and is of a higher grade in penicillin-resistant pneumococci than in isolates that are penicillin susceptible.[158] Even in penicillin-intermediate or penicillin-resistant strains that retain in vitro susceptibility to chloramphenicol, the clinical response to chloramphenicol in meningitis is poor. Some investigators have suggested that such bacteria express high minimal bactericidal concentrations to chloramphenicol; as a result, concentrations of drug achieved in the cerebrospinal fluid with routine dosing are lower than those required for good outcomes in central nervous system infections.[113]

Chloramphenicol retains excellent activity against most strains of *N. meningitidis*. However, investigators described meningococcal strains from Vietnam, Paris, and Australia that possessed high-level resistance to chloramphenicol.[119,400] Chloramphenicol resistance in *Salmonella* spp., a fourth group of organisms that causes disseminated disease and meningitis in pediatric patients, varies geographically. Resistance, with a prevalence frequently exceeding 50 percent, usually is detected in developing countries,[202] where chloramphenicol has been a readily available oral agent for typhoidal and nontyphoidal *Salmonella* infections for decades. In most *Salmonella* isolates, chloramphenicol resistance occurs coincident with resistance to multiple other antibiotics, particularly ampicillin, sulfonamides, tetracycline, and some of the older aminoglycosides. Chloramphenicol resistance has become increasingly common in industrialized nations as well.[60,408,462] In the United States, the strain *Salmonella typhimurium* DT104, which similarly coexpresses resistance to several classes of antibiotics including chloramphenicol, has become a widespread health hazard.[1,453]

Mechanisms of Resistance

The antibacterial activity of chloramphenicol is conferred by its interference with the peptidyl transferase region of the 50S prokaryotic ribosome. The principal mechanism of resistance is through the expression of the modifying enzyme chloramphenicol acetyltransferase (CAT), which catalyzes the acetylation of the C3-hydroxy group of the drug and thereby prevents its binding to the bacterial ribosome.[397] CATs actually represent a family of enzymes. Many CATs share chemical properties and structural homologies, especially around the active site.[397] CATs frequently reside on plasmids or transposons that carry other antibiotic-resistance determinants.[455] In *Salmonella* in particular, the chloramphenicol-resistance gene frequently is encoded on a class 1 integron incorporated in the so-called *Salmonella* Genomic Island 1 (SGI1), which includes multiple antibiotic-resistance cassettes.[88,288] SGI1 is transmissible and has been identified in many different *Salmonella* serovars.

Alternative mechanisms of resistance to chloramphenicol also have been identified in certain gram-negative species. In most of these organisms, resistance is linked to decreased intracellular accumulation of drug. In chloramphenicol-resistant *Pseudomonas*, this phenomenon has been associated with the overproduction of an approximately 50-kd outer-membrane protein,[236] which in the past led to the speculation that entry of drug into the bacterium was diminished by an abnormal porin. More recently, however, cell membrane proteins of this size have been identified as components of complex efflux apparatus that include both the pump itself and proteins that channel the extruded substance across the periplasmic space and through the outer membrane.[326] More

*References 46, 125, 191, 212, 310, 369, 377, 391, 402, 463.

direct evidence of such multidrug-resistant efflux pumps have been identified in chloramphenicol-resistant *E. coli*,[149] *Pseudomonas*,[236] *Stenotrophomonas*,[491] and *Salmonella*.[25,49,338] Usually, these pumps result in coresistance to multiple other antimicrobial agents, including tetracycline, sulfonamide, aminoglycosides, quinolones, and selected detergents.

pharmacodynamics) and drug disposition (i.e., pharmacokinetics) is of critical importance in the selection and evaluation of any anti-infective drug regimen.

The *pharmacokinetic-pharmacodynamic interface* reflects an association between two determinants of drug effect—delivery of drug to the site of action and the intrinsic activity of a drug to alter cellular function once it reaches that site. In much of the contemporary literature in clinical pharmacology and therapeutics, *kinetics* generally is associated with a description of the rate processes associated with drug absorption, distribution, metabolism, and excretion (ADME). Although accurate in its definition concerning the movement of drugs into and out of the body, kinetics as a determinant of drug effect must be viewed in a much broader context, specifically, the sojourn and fate of a drug molecule in both the extracellular and intracellular milieu. Although understanding this facet of drug behavior admittedly is difficult because of a relative inability in the clinical context to track the intracellular fate of a drug in humans, achieving a high degree of control over anti-infective therapy by the application of well-characterized and understood kinetic principles is quite possible.

The focus of this chapter is on the pharmacologic considerations necessary for the prudent use of anti-infective agents in pediatric patients, specifically, the pharmacokinetic and pharmacodynamic principles that, if embraced, can be the key to optimizing drug treatment and maximizing therapeutic efficacy and safety. The pediatric patient presents a particular challenge to the clinician. Although pediatric practitioners generally recognize that "children are not just miniature adults," one may not appreciate that the dramatic changes associated with normal human growth and development can, and many times do, exert a profound influence on drug disposition, drug action, and, ultimately, therapeutic outcome.[113] Failure to compensate for developmental differences in pharmacokinetics in the context of therapeutic drug use in pediatrics can increase the risk of occurrence of adverse drug effects associated with either overdose (i.e., drug toxicity) or underdose (i.e., lack of efficacy).[78,113]

In the following sections of this chapter the basic principles are presented that are required to understand the pharmacokinetic-pharmacodynamic interface in pediatrics, namely, general principles in pharmacokinetics, the impact of development on drug disposition, the pharmacokinetic determinants of drug action, and methods to facilitate clinical integration of the pharmacokinetic and pharmacodynamic properties necessary to optimize anti-infective therapy.

PHARMACOKINETIC DETERMINANTS OF EXPOSURE

Implicit in the production of any pharmacologic effect is the association of a drug molecule with one or more receptors and the subsequent propagation of intracellular events that ultimately translate into drug action. In general terms, successful drug-receptor interactions are characterized by three principles: (1) *avidity*, the ability of a drug to combine with a receptor; (2) *affinity*, the physical combination of a drug with a receptor, and (3) *intrinsic activity*, the ability of the drug-receptor combination to generate one or more "impulses" or "signals" capable of activating biologic effector systems. The primary determinants of both avidity and affinity reside with the maintenance of structural specificity of both the drug and receptor to ensure that an association with one or more physicochemically distinct active sites can occur. Simply stated, a drug molecule must fit into a receptor as a key fits into a lock before intrinsic activity becomes a possibility. The receptor or receptors thus will function in the role of cellular targets for drug molecules when an effective combination is required for drug effect and, ultimately, therapeutic efficacy. The pharmacodynamic implications of these targets are discussed in the second half of this chapter and in other chapters in this textbook in the context of specific anti-infective agents.

The onset and offset of drug action are determined not only by receptor-modulated intrinsic activity but also by receptor occupancy. In almost all instances, these events are both concentration and time dependent. Hence, the disposition of a drug in the body (e.g., ADME) becomes the "driver" for its pharmacodynamics. This action is particularly true for anti-infective drugs when the therapeutic target, the infecting organism, must be exposed to a sufficient concentration of pharmacologically active (i.e., free) drug for a period sufficient for drug binding to critical cellular elements (e.g., penicillin-binding proteins [PBPs], intracellular enzymes) to occur and for subsequent disruption of normal cellular function (e.g., inhibition of protein biosynthesis, inhibition of cell wall synthesis) to result in cellular demise. Thus, the clinical determinants of drug efficacy (and safety), such as proper selection of both dose and dosing interval relative to the intrinsic sensitivity of the infecting pathogen or pathogens, and factors that determine delivery of the drug to the site or sites of infection embody the importance of pharmacokinetics in the selection and clinical use of anti-infective drugs.

BASIC TERMS

A complete discussion of pharmacokinetics is beyond the scope of this chapter because it would require a description of theory and a presentation of relatively sophisticated mathematic concepts. This information can be found in many excellent textbooks that provide both theoretical[77] and conceptual[113,190,237] presentations of pharmacokinetics and through Internet-based programmed instruction courses.[25] However, well within the scope of this chapter are a definition and glossary of pharmacokinetic terms sufficient to equip the reader with a conceptual, working knowledge of this pharmacotherapeutic tool. These definitions and concepts are presented as follows:

Absolute bioavailability (F) is the extent or fraction of drug absorbed after extravascular administration. It is determined by comparing the area under the plasma concentration versus time curve (AUC) after administration of an oral dose of a drug with the AUC after

administration of an intravenous dose (e.g., $F = AUC_{PO} \times dose_{IV}/AUC_{IV} \times dose_{PO}$).

Absorption of drugs describes the process of drug uptake from a site of extravascular administration (e.g., oral, intramuscular, subcutaneous, intraperitoneal, intraosseous, intratracheal, intravaginal, intraurethral, sublingual, buccal, rectal, and dermal) into the systemic circulation. Drug absorption is conceptualized most accurately by considering both rate (e.g., absorption half-life, time to peak concentration) and extent (e.g., bioavailability), either of which can be influenced by biopharmaceutical (e.g., drug formulation), physicochemical (e.g., pH, solubility, hydrophilicity and lipophilicity, protein binding, complexation characteristics with food or drugs), and physiologic factors (e.g., barrier integrity, motility, volume and pH of body fluids at the absorptive site, protein-binding capacity, degradation/biotransformation potential).

Area under the curve (AUC) is, conceptually, a measure of both the extent of drug absorbed and its persistence in the body. It is the integral of drug blood levels over time from zero to either a predetermined postdose time point (i.e., $AUC_{0\rightarrow tx}$) or extrapolated to infinity (i.e., $AUC_{0\rightarrow\infty}$) by using the apparent terminal elimination rate constant (similarly calculated from the observed plasma concentration versus time plot) (Fig. 234-1). AUC is therefore a pharmacokinetic parameter that is both time and concentration dependent.

Bioequivalence of a drug product is achieved if its extent and rate of absorption are not significantly different (i.e., within 80% to 125%) from those of a reference standard drug product when administered at the same molar dose. Bioequivalence is a pharmacokinetically determined parameter and does not entail a relative comparison of drug action or efficacy. Therefore, if a drug product (e.g., a generic drug) produces a rate and extent of absorption sufficiently similar to those of the reference formulation, the effect and toxicity profiles of the two drugs are assumed to be virtually identical.

Biopharmaceutics deals with the physical and chemical properties of the drug substance, the dosage form, and the body, as well as the biologic actions of a drug or drug product after administration. Biopharmaceutical considerations (e.g., rate and extent of the disintegration or dissolution of a dosage form, liberation of the active drug from a dosage form, solubility or binding of the drug at the site of absorption) can be rate limiting for drug absorption or bioavailability, or for both, and thus may limit the efficacy of drug therapy.

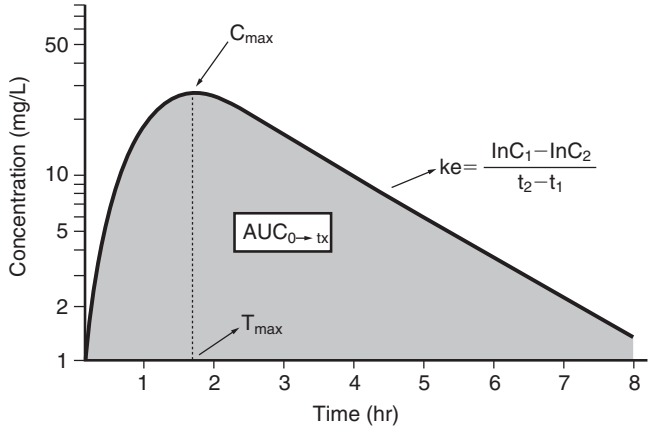

FIGURE 234-1 ■ Representative plasma concentration versus time curve. Illustrated are commonly referenced pharmacokinetic parameters, including AUC, area under the curve; C_{max}, maximal plasma concentration; ke, elimination rate constant; and T_{max}, time to achieve maximal plasma concentration.

Clearance (Cl) of a drug is represented conceptually by the volume of blood from which a certain amount of unmetabolized drug is removed (i.e., cleared) per unit of time by any and all pathways capable of drug removal (e.g., renal, hepatic, biliary, pulmonary, breast milk, sweat). In pharmacokinetics, clearance generally is represented as total-body (or plasma) clearance, renal clearance (Cl_{ren}), or nonrenal clearance (Cl_{nr}). Clearance is determined easily from knowledge of the drug dose, and AUC and can be calculated as follows:

$$Cl = Dose\ (mg/kg)/AUC\ (mg/L \times hr)$$

where AUC can represent either the $AUC_{0\rightarrow tx}$ for single-dose administration or the AUC from time zero to the end of the dosing interval at steady state (i.e., $AUCss_{0\rightarrow\tau}$). Calculation of renal clearance requires a complete, quantitative collection of urine (usually over the course of 24 hours) to determine the amount of drug excreted (Ae) unchanged. Nonrenal clearance generally is determined as the difference between total body clearance and renal clearance. For drug administration *by any extravascular route*, calculation of clearance yields an apparent value (e.g., Cl/F) in that it must be corrected for the extent of the drug dose absorbed (i.e., the bioavailability) from the site of administration.

A *compartment* in pharmacokinetics represents a *hypothetical space* into and out of which drug partitions as a function of time. Compartment *models* are used in pharmacokinetics to characterize the relationship between drug dose and concentration as a function of time. The most simple of all pharmacokinetic models is a *one-compartment open model* in which the only applicable rate processes represent drug ingress and egress from a single theoretical or central space. A *two-compartment model* has been used to characterize the disposition of many anti-infective agents in both pediatric and adult subjects. This particular model is composed of a central compartment and a peripheral compartment, both of which represent the various fluids and tissues where a drug may reside. Although a compartment often may not correspond to a true physiologic space that can be characterized by a specific volume of biologic fluid, compartment models can be used to conceptualize both drug distribution between physiologic spaces and elimination from the body. In the two-compartment model, for example, the central compartment often is used to represent a drug resident within the intravascular space and the highly exchangeable extracellular fluid of tissues and organs that are well perfused, whereas the peripheral compartment represents drug distribution to intracellular fluid and tissues and organs that are less well perfused and, in some instances, the association of the drug (e.g., binding) to specific tissues or tissue components. In all instances, compartmental models oversimplify the true processes of

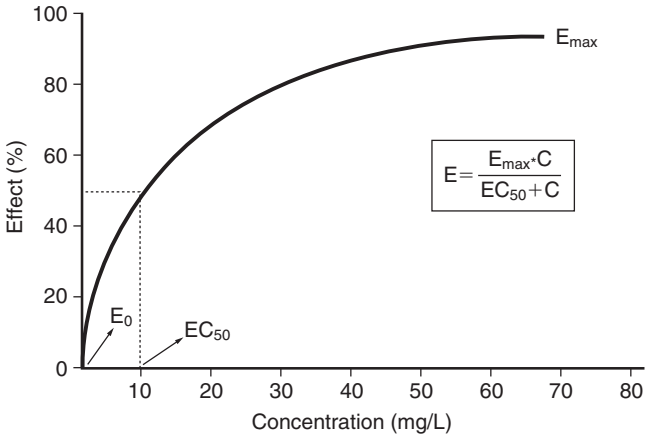

FIGURE 234-2 ■ Representative nonlinear concentration (C) versus effect profile. Emax, maximal effect; EC50, drug concentration for which the observed effect is 50 percent of the maximal effect.

ADME. However, they have been demonstrated repeatedly to be useful as a reliable means to model, and therefore predict, the relationship between drug dose and concentration in both plasma and tissue.

Disposition refers collectively to the processes of ADME, all of which occur simultaneously after administration of a drug, as opposed to being discrete pharmacologic events.

Dose-response curve is a graphic representation of the pharmacologic effect as a function of either the drug dose or the concentration of the drug. A log dose-response curve is often sigmoidal, whereas a cartesian concentration-effect curve is hyperbolic (Fig. 234-2). Theoretically, a drug concentration of zero indicates no drug effect (i.e., E_0). As a drug travels to and interacts with a receptor, the effect (E) increases in a concentration-dependent manner (i.e., E [(E_{max} C)/(E_50 + C)]) to a point at which a maximal effect (E_{max}) is attained and above which higher drug concentrations fail to enhance the effect. A pharmacologically important term that can be derived easily from a concentration-effect curve is the EC_{50}, or the drug concentration for which the observed effect is 50 percent of the E_{max}.

Elimination half-life of a drug is the time necessary to reduce the drug concentration (in blood serum or plasma) by 50 percent after absorption is complete and distribution between body compartments has attained equilibrium. Loss of drug from the body, as represented by the elimination half-life, reflects elimination of the administered parent drug molecule (i.e., not its metabolites) by metabolism, urinary excretion, or other pathways capable of resulting in elimination of drug. Accordingly, many individuals use elimination half-life as a surrogate indicator of drug clearance. Such a determination should be made cautiously because this particular pharmacokinetic parameter is dependent on both clearance and the apparent volume of distribution (VD), as illustrated by the following equation: $t_{1/2}$ elimination = [(0.693 × VD)/Cl], where $t_{1/2}$ is half-life. Practically speaking, the elimination half-life is an important pharmacokinetic parameter because it can be used to determine the period of time required for a drug dosing regimen to produce steady-state plasma concentrations (e.g., 5 × $t_{1/2}$ elimination) and the dosing interval required to produce a desired excursion (i.e., peak and trough) in plasma drug concentrations.

First-pass effect describes a phenomenon whereby drugs may be metabolized or chemically degraded (or both) after extravascular administration before they reach the systemic circulation. Specific examples include biotransformation of selected drugs (e.g., cytochrome CYP3A4 substrates) in the enterocyte and nonenzymatic hydrolysis of an active drug (e.g., aspirin) in the lumen of the gastrointestinal tract (e.g., stomach, intestine, rectum). Drugs subject to a first-pass effect generally have a reduced rate or extent of relative bioavailability, or both, when compared with that achieved by parenteral administration.

Protein binding is the phenomenon that occurs when a drug (or metabolite) combines with plasma or extracellular or tissue proteins to form a drug-protein complex. In general, drug-protein binding usually is nonspecific and depends on the drug's affinity for the protein molecule (i.e., binding site), the number of protein-binding sites, and the drug and protein concentrations. With few exceptions, drugs that are bound to proteins are pharmacologically inactive and cannot be metabolized or excreted readily. The pharmacokinetic consequences of drug-protein binding can influence the drug dose versus the plasma concentration versus the effect relationship. For example, drugs with extensive tissue binding have apparent volumes of distribution that are far in excess of the total-body water space and, in general, have relatively long elimination half-lives. Conditions in which intravascular proteins escape to extravascular sites (e.g., nephrotic syndrome, severe burns, ascites) can increase the apparent volume (and elimination half-life) of drugs that are extensively (i.e., >70%) bound to albumin.

Relative bioavailability reflects the extent of drug absorbed from one dosage form given by an extravascular route of administration in comparison to a dose of a "standard" drug formulation administered by the same route. Generally, it reflects the relative extent of systemic availability (F) and is calculated by comparing the AUC of the test regimen relative to the standard formulation (e.g., F = AUC_{test} × $dose_{standard}$/$AUC_{standard}$ × $dose_{test}$).

Steady state reflects the level of drug accumulation in the blood and tissue after multiple doses when input (i.e., the amount of drug placed into the systemic circulation) and output (i.e., drug clearance) are at equilibrium. When drugs are given at fixed doses and dosing intervals, the steady-state concentrations fluctuate between a maximum (C_{max}) and minimum (C_{min}) within a given dose interval that is identical between doses, provided that the size of the dose, method of administration, dosing interval, or drug pharmacokinetics (or any combination of these parameters) does not change. For drugs that follow first-order pharmacokinetics, steady-state plasma concentrations for a given dosing regimen are attained over a period of time that corresponds to four to five times the elimination half-life. In general, the pharmacokinetics of a drug at steady state provides the most accurate correlate for examining drug effect.

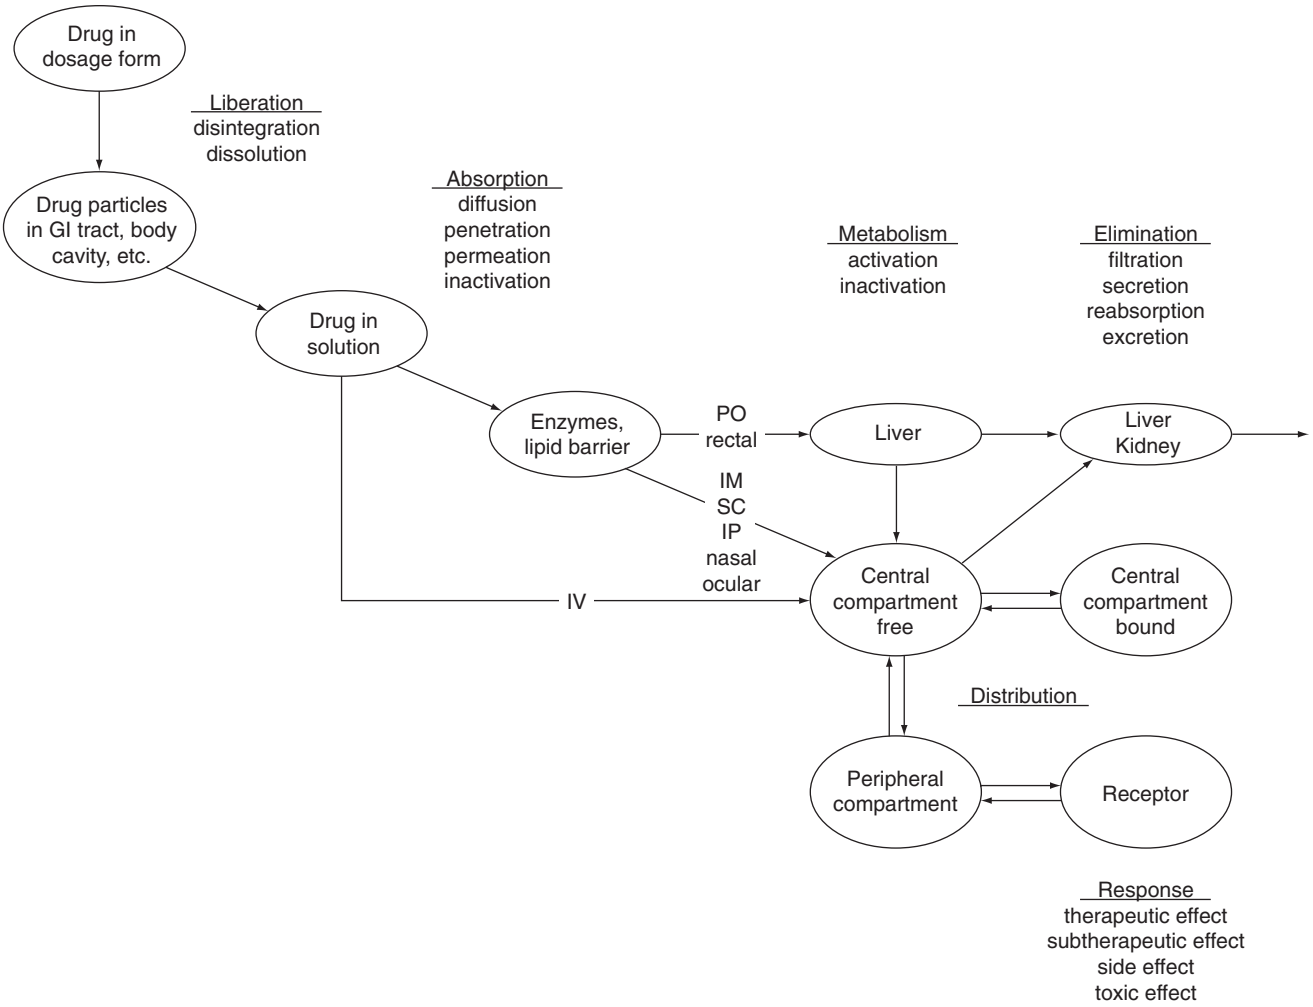

FIGURE 234-3 ■ Graphic representation of the pharmacokinetic-pharmacodynamic interface. GI, gastrointestinal; IM, intramuscular; IP, intraperitoneal; PO, oral; SC, subcutaneous.

Volume of distribution *(apparent volume of distribution)* (VD) represents a hypothetic volume of body fluid that would be required to dissolve the total amount of a drug at the same concentration as that found in the blood and is illustrated by the following equation:

$$VD = Dose/Cp^0$$

where Cp^0 represents the highest attainable plasma concentration after the administration of a single dose. As a proportionality constant, the VD is a determinant of plasma drug concentrations attained after administration of a given drug dose. For drugs that are not distributed extensively or that bind with great affinity to proteins and tissues, the apparent VD may correspond dimensionally to physiologic or anatomic body spaces (e.g., VD <0.1 L/kg approximates the intravascular space, 0.1 to 0.3 L/kg approximates the extracellular space, 0.6 to 0.7 L/kg approximates the total-body water space), which, when altered by disease or development, or by both, will influence the apparent VD and thus the achievable concentration for a given drug.

A working knowledge of these pharmacokinetic definitions allows one to have an understanding of the relationships among drug dose, concentration, and effect. The use of knowledge related to the physicochemical and pharmacologic properties of a drug, the impact of isolated or concurrent variables on drug disposition, and predictors of pharmacodynamics or drug response enables the clinician to optimize the selection of agents and dosing regimens and thus individualize drug therapy. To accomplish this goal, it is imperative that the relationship between drug pharmacokinetics and pharmacodynamics not be compartmentalized but rather, as illustrated in Figure 234-3, be conceptualized as multifactorial, in which the determinants of drug concentration and effect are dynamic and change as a function of a disease state and drug therapy.

IMPACT OF ONTOGENY ON PHARMACOKINETICS

Development represents a continuum of biologic events that enable adaptation, somatic growth, neurobehavioral maturation, and, eventually, reproduction. The impact of development on the pharmacokinetics of a given drug is

determined, to a great degree, by age-related changes in body composition and the acquisition of function in organs and organ systems that are important in determining drug metabolism and excretion. Although classifying pediatric patients on the basis of postnatal age (e.g., neonates, ≤1 month of age; infants, 1 to 24 months of age; children, 2 to 12 years of age; and adolescents, 12 to 18 years of age) often is convenient for providing drug therapy, recognizing that the changes in physiology are not linearly related to age and may not correspond to these age-defined breakpoints is important. In fact, the most dramatic changes in drug disposition occur during the first 18 months of life, when the acquisition of organ function is most dynamic. Additionally, the pharmacokinetics of a given drug may be altered in pediatric patients as a result of intrinsic (e.g., gender, genotype, ethnicity, inherited diseases) or extrinsic (e.g., acquired disease states, xenobiotic exposure, diet) factors that may occur during the first 2 decades of life.

Selection of an appropriate drug dose for a neonate, infant, child, or adolescent requires an understanding of the basic pharmacokinetic properties of a given compound and how the process of development affects each facet of drug disposition. Accordingly, conceptualizing pediatric pharmacokinetics by examining the impact of development on the physiologic variables that govern ADME is most useful.

Drug Absorption

The rate and extent of gastrointestinal absorption depend primarily on pH-dependent passive diffusion and motility of the stomach and small intestine, both of which control transit time. In full-term neonates, gastric pH ranges from 6 to 8 at birth and drops to 2 to 3 within the first few hours. After the first 24 hours of extrauterine life, gastric pH increases to 6 to 7 as a result of immaturity of the parietal cells. A relative state of achlorhydria remains until adult values and diurnal patterns of gastric pH are reached at 20 to 30 months of age. Although basal gastric acid output can be quite similar in neonates, young infants, and adults, stimulated acid output can be threefold to fourfold higher than that seen in adults.[53,54]

In neonates, gastrointestinal transit time is prolonged as a result of reduced motility and peristalsis. Gastric emptying is both irregular and erratic and only partially dependent on feeding. Gastric emptying rates approximate adult values by the time the infant reaches 6 to 8 months of age. During infancy, intestinal transit time generally is reduced relative to adult values because of increased intestinal motility.[113] In contrast to developmental changes in motility, histologic examination of the luminal absorptive surface suggests that the adult pattern of architecture (and hence absorptive surface area relative to body size) is present at birth.[82,233] In neonates and young infants, additional factors, including diminished splanchnic blood flow, immature biliary function, variable microbial colonization, and an apparent reduction in the activity of intestinal drug-metabolizing enzymes, may play a role in intestinal drug absorption.[41,183]

These developmental changes in gastrointestinal function and structure in the neonatal period and early infancy produce alterations in drug absorption that are quite predictable. In general, the oral bioavailability of acid-labile compounds (e.g., β-lactam antibiotics) is increased, whereas that of weak organic acids (e.g., phenobarbital, phenytoin) is decreased. For orally administered drugs with limited water solubility (e.g., phenytoin, carbamazepine), the rate of absorption (i.e., T_{max}) can be altered dramatically as a result of changes in gastrointestinal motility.[183] The pharmacokinetics of the antiviral agent pleconaril similarly provides an example of developmental differences in drug absorption. After administration of a 5-mg/kg dose, the AUC was much lower in neonates than either children or adults, thus demonstrating that the extent of pleconaril bioavailability in neonates was reduced. The reason for this difference may be attributed to the lipid-based pleconaril formulation and to developmental differences in the ability to absorb lipids as a consequence of biliary immaturity and reduced lipase secretion in neonates.[115]

In neonates and young infants, both rectal and percutaneous absorption is highly efficient for properly formulated drug products. The bioavailability of many drugs administered by the rectal route is increased as a result of not only efficient translocation across the rectal mucosa but also a reduced first-pass effect caused by the immaturity of a number of drug-metabolizing enzymes in the liver. Both the rate and extent of percutaneous drug absorption are increased because of the thinner and better hydrated stratum corneum in young infants. As a consequence, systemic toxicity can occur with the percutaneous application of some drugs (e.g., hexachlorophene) to seemingly small areas of skin during the first 8 to 12 months of life. In contrast to older infants and children, the rate of bioavailability for drugs administered by the intramuscular route may be altered (i.e., delayed T_{max}) more than the extent of absorption in a neonate. This developmental pharmacokinetic alteration is the consequence of relatively low muscular blood flow in the first few days of life, the relative inefficiency of muscular contractions (useful in dispersing an intramuscular drug dose), and an increased percentage of water per unit of muscle mass.[183]

Developmental differences in drug absorption among neonates, infants, and older children are summarized in Table 234-1. The data contained therein reflect developmental differences that may be expected to occur in healthy pediatric patients. Certain conditions or disease states that could modify the function or structure, or both, of the absorptive surface area, gastrointestinal motility, or systemic blood flow can further affect either the rate or the extent of absorption for extravascularly administered drugs in pediatric patients.

Distribution

Development is associated with marked changes in body composition as reflected by examination of total-body water, extracellular water, and stores of body fat (Fig. 234-4). The most dynamic changes occur in the first year of life, with the exception of total-body fat, which has a distinctly different pattern in male and female children. Furthermore, the adipose tissue of neonates may contain

TABLE 234-1 **Summary of Drug Absorption in Neonates, Infants, and Children***

	Neonates	Infants	Children
Physiologic Alteration			
Gastric emptying time	Irregular	Increased	Slightly increased
Gastric pH	>5	4 to 2	Normal (2-3)
Intestinal motility	Reduced	Increased	Slightly increased
Intestinal surface area	Reduced	Near adult	Adult pattern
Microbial colonization	Reduced	Near adult	Adult pattern
Biliary function	Immature	Near adult	Adult pattern
Muscular blood flow	Reduced	Increased	Adult pattern
Skin permeability	Increased	Increased	Near adult pattern
Possible Pharmacokinetic Consequences			
Oral absorption	Erratic: reduced	Increased rate	Near adult pattern
Intramuscular absorption	Variable	Increased	Adult pattern
Percutaneous absorption	Increased	Increased	Near adult pattern
Rectal absorption	Very efficient	Efficient	Near adult pattern
Presystemic clearance	Less than adult	Greater than adult	Greater than adult (increased rate)

(From Ritschel WA, Kearns GL. Pediatric pharmacokinetics. In: Ritschel WA, Kearns GL, editors. *Handbook of basic pharmacokinetics.* 6th ed. Washington, D.C.: American Pharmaceutical Association; 2004, p. 227-40.)

as much as 57 percent water and 35 percent lipids, whereas values in adults approach 26.3 percent and 71.7 percent, respectively.[183]

In addition to age-related alterations in body composition, several physiologic changes that occur during the neonatal period are capable of altering the plasma protein binding of drugs (Table 234-2). In neonates, the free fraction of drugs that are bound extensively to circulating plasma proteins is increased markedly, largely because of lower concentrations of drug-binding proteins, reduced binding affinity of these proteins, the presence of a relatively acidic plasma pH, and endogenous competing ligands (e.g., bilirubin, free fatty acids). This consideration is exemplified by ceftriaxone, a weak acid that is approximately 95 percent bound to albumin in adults but only 70 percent bound in neonates and thus is capable of producing significant displacement of bilirubin.[92,147] The reduced plasma protein binding in combination with absolute and relative differences in the size of various body compartments (e.g., total-body water, extracellular fluid, composition of body tissues) frequently influences (i.e., increases) the apparent VD for many drugs and also their localization (i.e., both uptake and residence) in tissue, which, in turn, can alter their plasma elimination half-life.

Renal Excretion

The renal excretion of many drugs is directly proportional to age-dependent patterns in the acquisition of renal function, primarily glomerular filtration and active tubular secretion. Accordingly, developmental differences in renal function may serve as a major determinant of drug clearance in neonates and young infants for compounds that are not metabolized extensively.[183]

In preterm infants, renal function is reduced dramatically because of the continued development of functioning nephron units (i.e., nephrogenesis). In contrast, the acquisition of renal function in a term neonate represents, to a great degree, the recruitment of fully developed nephron units. In both term neonates and preterm infants who have birth weights greater than 1500 g, glomerular filtration rates increase dramatically during the first 2 weeks of postnatal life (Fig. 234-5). This particular dynamic change in function is a direct consequence of postnatal adaptations in the distribution of renal blood flow (i.e., medullary distribution to the corticomedullary border) and results in a dramatic recruitment of functioning nephron units.[113] In addition, a glomerular-tubular imbalance exists in which the maturation of the glomerular function is more advanced than is the proximal tubular

TABLE 234-2 **Plasma Protein Binding and Drug Distribution***

	Neonates	Infants	Children
Physiologic Alteration			
Plasma albumin	Reduced	Near normal	Near adult pattern
Fetal albumin	Present	Absent	Absent
Total protein	Reduced	Decreased	Near adult pattern
Serum bilirubin	Increased	Normal	Normal adult pattern
Serum free fatty acids	Increased	Normal	Normal adult pattern
Blood pH	7.1-7.3	7.4 (normal)	7.4 (normal)
Possible Pharmacokinetic Consequences			
Free fraction	Increased	Increased	Slightly increased
Apparent volume of distribution			
Hydrophilic drugs	Increased	Increased	Slightly increased
Hydrophobic drugs	Reduced	Reduced	Slightly decreased
Tissue-to-plasma ratio	Increased	Increased	Slightly increased

secretion. This imbalance may persist for up to 6 to 10 months of age, when both tubular function and glomerular function approach values approximately equal to those observed in healthy, young adults.[183]

The impact of development on each of the components of renal function can be characterized by a definable pattern during the first year of life (see Fig. 234-5).[167] Accordingly, the renal handling and, hence, excretion and elimination characteristics of virtually any drug in neonates, infants, and children can be predicted largely by considering the ontogeny of renal function and the specific pharmacologic characteristics of a given drug with regard to its renal excretion (e.g., routes of renal excretion, the percentage of a given dose excreted unchanged in urine) in adults. For antimicrobial agents, the impact of the ontogeny of the renal function on pharmacokinetics is reflected largely by alterations in the plasma drug clearance. As summarized by van den Anker and Kearns,[223] the elimination half-life of antimicrobial agents from different classes that share predominantly renal pathways of excretion is increased substantially in neonates and young infants (Table 234-3). This increase is not the case for antimicrobial and other agents that are not excreted primarily by the kidneys (e.g., ceftriaxone; see Table 234-3).

Metabolism

Simply stated, drug metabolism (or biotransformation) involves the modification of a drug molecule by one

or more enzymes such that the hydrophilicity of the product is increased relative to the parent drug, thus enhancing elimination and excretion. In most instances, drug metabolism creates products that are either less pharmacologically active than is the parent drug (e.g., desacetylcefotaxime) or devoid of pharmacologic activity altogether (e.g., cefotaxime lactone metabolites).[112] In other instances, metabolism can result in drug bioactivation and produce metabolites with pharmacologic activity from an inactive parent drug (i.e., prodrug) or generate metabolites that can result in cellular toxicity in the host (e.g., sulfamethoxazole's nitroso and hydroxylamine reactive metabolites, acetaminophen's NAPQI reactive metabolite).

Virtually every tissue has some ability to carry out drug biotransformation reactions. Although the liver is quantitatively the most important organ capable of drug metabolism, the small intestine, lungs, skin, and kidneys also have substantial drug biotransformation activities. In infants, children, and adolescents, developmental variations in drug metabolism have been associated with age, sex, maturation, and genetic constitution. For compounds that are extensively metabolized, developmental differences in drug metabolism can serve as the primary determinant for age-appropriate dose selection.[131] Much of the existing information regarding the impact of ontogeny on drug metabolism has been derived as a byproduct of pharmacokinetic investigations designed, in part, to determine whether age-dependent differences in drug disposition were evident.[113] The following paragraphs highlight important general issues regarding drug metabolism and its relationship with development.

PHASE I PATHWAYS

Phase I biotransformation reactions include oxidation, reduction, and hydrolysis reactions that, in general, introduce or unmask a functional group (e.g., hydroxyl, amine, sulfhydryl) that renders a drug more polar. Quantitatively, the P-450 cytochromes are the most important of the phase I enzymes and represent a superfamily of heme-containing proteins that catalyze the metabolism of many lipophilic endogenous substances (e.g., steroids, fatty acids and fat-soluble vitamins, prostaglandins, leukotrienes, and thromboxanes) and exogenous compounds. In humans, the P-450 cytochromes can be divided functionally into two distinct classes: steroidogenic enzymes expressed in specialized tissues, such as the adrenal glands, gonads, and placenta; and enzymes involved in the metabolism of drugs, pesticides, and environmental contaminants. P-450 cytochromes that have been identified as important in human drug metabolism are found predominantly in the *CYP1*, *CYP2*, and *CYP3* gene families.[131]

As reviewed by Leeder and Kearns,[131] considerable interindividual variability exists in the hepatic expression of P-450 enzymes, and, for a given individual, the pathway and rate of a compound's metabolic clearance constitute that individual's unique phenotype with respect to the forms and amounts of P-450 isoforms expressed. Of the P-450 cytochromes involved in drug biotransformation, CYP2C19, CYP2C9, and CYP2D6 are examples of isoforms that are polymorphically expressed in humans. Polymorphic expression of CYP1A2 and CYP3A4 has been reported in the literature but not definitively established with regard to functional consequences. Within a P-450 subfamily, several isoforms can exist (e.g., CYP3A4, CYP3A5, and CYP3A7), each of which can demonstrate substrate specificity and a distinct developmental pattern with regard to enzyme activity. In addition, certain P-450 cytochromes (e.g., CYP3A4) can work cooperatively with transporters (e.g., MDR-1 or P-glycoprotein) located in distinct cells or tissues to alter the availability of specific drugs to the systemic circulation (e.g., first-pass metabolism of CYP3A4 substrates in the enterocyte). Moreover, for certain polymorphically expressed P-450 cytochromes (e.g., CYP2C19, CYP2D6), enzyme activity has been shown to vary as a consequence of racial or ethnic origin[179] and, within a given phenotypic distribution (e.g., extensive metabolizers for CYP2D6), as a function of single nucleotide polymorphisms that exist in either the gene or its regulatory regions.[177] Finally, throughout development, the activities of the P-450 cytochromes can vary widely (e.g., 5- to 25-fold) among individuals of the same phenotype,[131] an important factor with respect to the ability for induction or inhibition and, thus, the prediction of drug-drug or drug-xenobiotic interactions in vivo.

PHASE II PATHWAYS

In general, phase II reactions involve the coupling of a drug or drug metabolite with an endogenous substance to enhance its hydrophilicity further and to facilitate drug excretion in either urine or bile. These reactions require the participation of specific transferase enzymes (e.g., epoxide hydrolase, glucuronosyltransferases, glutathione *S*-transferases, sulfotransferases, *N*-acetyltransferases, methyltransferases, transacylases) and high-energy, activated endogenous substances. Although most conjugation reactions result in drug detoxification, examples of bioactivation by phase II enzymes do exist.[182] Similar to what has been found for certain of the P-450 cytochromes, different isoforms of phase II enzymes also occur in humans. This finding is exemplified by the review of de Wildt and colleagues,[42] who described substrate specificity for 10 different glucuronosyltransferase isoforms in humans and known polymorphisms in 5 different isoforms of this enzyme. The impact of age on the disposition of several glucuronosyltransferase substrates (e.g., morphine, acetaminophen, zidovudine, chloramphenicol) suggests that isoform-specific, age-related differences in activity occur to a degree sufficient to produce profound effects on drug clearance that translate directly into age-specific differences in a drug dose.[42]

Normal growth and development can have a profound effect on the activity of drug-metabolizing enzymes. Failure to recognize important developmental differences in drug biotransformation and to appropriately compensate for them by individualizing drug dosing can lead to serious consequences. This is exemplified by the "gray baby syndrome" previously associated with

chloramphenicol, which is a life-threatening adverse drug reaction that was associated with supratherapeutic systemic drug exposure and, in some infants, produced cyanosis and cardiovascular collapse. The genesis of this particular toxicity resided with normal developmental reductions in the activity of the glucuronosyltransferase isoforms responsible for metabolizing chloramphenicol and the failure to appropriately adjust the dosing schedule to compensate for reductions in systemic clearance.[56,234] Traditionally, the impact of ontogeny for all enzymes was viewed as being extremely limited in neonates, rapidly increasing in the first year of life to levels in toddlers and older children that may exceed adult capacity, and declining to adult levels by the conclusion of puberty. Experimental and clinical data previously reviewed demonstrated that this theory is not accurate.[113,131] As illustrated by the summary data contained in Table 234-4, the impact of ontogeny on the activity of both phase I and phase II drug-metabolizing enzymes is very much a substrate- and isoform-specific event; development is one dynamic factor in a multitude of conditions (e.g., nutritional status, gender, diurnal variation, menstrual cycle, disease states/organ dysfunction, pregnancy, concomitant drug therapy) capable of altering the activity of drug-metabolizing enzymes and, thus, the clearance of drugs (and their metabolites) from plasma. Although discussion of the impact of ontogeny on the disposition (pharmacokinetics) of specific drugs is beyond the scope of this chapter, the clinician can use much of the information concerning specific enzymes provided in Table 234-4 as a tool to facilitate inquiry or clinical decision making, or both. It can be done simply by using readily available, updated information describing which enzymes are responsible for drug metabolism and then searching the published or unpublished (e.g., information available from pharmaceutical companies for drugs under development) literature for information describing the pharmacokinetics of the drug being considered.[59]

Clinicians must recognize that age-dependent differences in the activity of enzymes that catalyze drug biotransformation are not limited solely to P-450 cytochromes or the host of transferase enzymes responsible for phase II drug metabolism, and, in many cases, these differences represent a critical determinant for successful anti-infective drug therapy. This factor is exemplified by considering the example of two antimicrobial agents that have unique places in pediatric therapy: cefotaxime and linezolid. In the case of cefotaxime, non–P-450 enzymes (probably an esterase) capable of generating the active desacetylcefotaxime metabolite appear to be present and fully active by the third trimester of gestation.[117] Nonetheless, the elimination half-life of cefotaxime in neonates is approximately threefold greater (i.e., 3 to 4 hours) than that observed in older infants and children (i.e., 1 to 1.5 hours), a difference that permits extension of the dosing interval for the use of cefotaxime in neonates. The reasons for this developmental difference reside not with the enzymes responsible for generation of an active metabolite; instead, age-associated reductions in the activity of enzymes appear to be responsible for the generation of inactive metabolites of cefotaxime (e.g., cefotaxime lactone) and pathways involved in the renal clearance of desacetylcefotaxime.[116] Linezolid, an oxazolidinone antimicrobial approved in the United States for use in pediatric patients, undergoes extensive biotransformation in humans, not through a cytochrome P-450 enzyme but rather by nonselective chemical oxidation.[119] As demonstrated by Kearns and associates,[114] the mean plasma clearance of linezolid in children was

TABLE 234-4 **Developmental Patterns for the Ontogeny of Important Drug-Metabolizing Enzymes in Humans**

Enzyme(s)	Known Developmental Pattern
Phase I Enzymes	
CYP2D6	Low to absent in fetal liver but present at 1 wk of age; poor activity (i.e., 20% of adult) by 1 mo; adult competence by 1 to 3 yr of age
CYP2C9	Apparently absent in fetal liver; low activity in first 2 to 4 wk of life, with adult activity reached by approximately 6 mo; activity may exceed adult levels during childhood and declines to adult levels after conclusion of puberty
CYP1A2	Not present in appreciable levels in human fetal liver; adult levels reached by approximately 4 mo and exceeded in children at 1 to 2 yr of age; adult activity reached after puberty
CYP3A7	Fetal form of CYP3A that is functionally active (and inducible) during gestation; virtually disappears by 1 to 4 wk of postnatal life when CYP3A4 activity predominates but remains present in approximately 5% of individuals
CYP3A4	Extremely low activity at birth, reaching 30% to 40% of adult activity by 1 mo and full adult activity by 6 mo; may exceed adult activity between 1 and 4 yr of age and decrease to adult levels after puberty
Phase II Enzymes	
NAT2	Some fetal activity by 16 wk of gestation; poor activity between birth and 2 mo of age; adult phenotype distribution reached by 4 to 6 mo, with adult activity reached by 1 to 3 yr
TPMT	Fetal levels approximately 30% of adult values; in newborns, activity approximately 50% higher than in adults, with phenotype distribution approximating that of adults; exception is Korean children, in whom adult activity is seen by 7 to 9 yr of age
UGT	Ontogeny isoform specific; in general, adult activity reached by 6 to 24 mo of age
ST	Ontogeny isoform specific and appears faster than that for UGT; activity for some isoforms may exceed adult levels during infancy and early childhood

CYP, cytochrome P-450; NAT2, *N*-acetyltransferase-2; ST, sulfotransferase; TPMT, thiopurine methyltransferase; UGT, glucuronosyltransferase.

Modified from Leeder JS, Kearns GL. Pharmacogenetics in pediatrics: implications for practice. *Pediatr Clin North Am* 1997;**44**:55-7.

approximately threefold higher than that observed previously for adults, with the greatest increase noted in infants younger than 1 year. Given the mechanism of action for linezolid and properties that reflect time-dependent killing,[119] the clinical implications of the age-dependent pattern of increased plasma clearance for this drug in young infants and children suggest that for infections with selected pathogens that have relatively high (90%) minimal inhibitory concentration (MIC_{90}) values for the drug, shorter dosing intervals (e.g., every 8 hours) may be necessary to ensure sufficient exposure of the organism in blood and tissue through most of a dosing interval.[114]

PHARMACOKINETIC DETERMINANTS OF EFFECT

Collectively, the most important determinants of efficacy for anti-infective agents are the pharmacokinetic profile of the drug, the physicochemical and biochemical characteristics of the local environment (i.e., site of infection), and the susceptibility of the infecting organisms under local growth conditions. As previously reviewed by Barza,[14] the mechanisms and pharmacokinetics of drug transport to and accumulation at the site or sites of infection, as well as the subcellular localization of drugs, are critical to success and are poorly understood. In many circumstances, plasma drug concentrations may not be reflective of those in tissue. Pathophysiologic processes related to the host, the infection, and the physicochemical properties of the drug work in concert to regulate distribution into and retention of active drug at the site of infection. Because these considerations should be embraced by the clinician when a particular anti-infective drug is selected for treatment and its therapy is monitored for clinical evidence of success, some general examples are presented as follows.

In addition to age (as discussed earlier), many disease processes (e.g., trauma, malignancy, renal or hepatic disease) have an impact on both the quantity of circulating plasma proteins (e.g., albumin, α_1-acid glycoprotein) and their affinity to bind anti-infective agents. Given that only free drug is available to enter tissue, the degree of binding to protein components in the blood will affect tissue concentrations. Thus, despite the presence of total (i.e., free and bound) plasma drug concentrations well in excess of the MIC, these concentrations may not be predictive of concentrations of highly bound (i.e., >70%) drug at the site of infection. Properties of the capillary bed feeding the site of infection also dictate drug penetration. Highly vascularized tissue with a large ratio of capillary surface area to volume can be expected to accumulate higher drug concentrations than can tissue that is poorly vascularized, principally because of the rate and extent to which drug can be delivered to the site. As with protein binding, variability in capillary density may be a function of disease (e.g., severe atherosclerosis, diabetes), infection (e.g., abscess, cardiac vegetation), and age, and it should be expected to have an impact on drug delivery. Similarly, tissues with tight junctions and few fenestrations (e.g., eye, central nervous system [CNS]) afford lower tissue concentrations, given that drug entry is restricted to transport across the lipid bilayer of the endothelial cell (i.e., transcellular vs. paracellular transport). Here, adequate drug penetration is restricted to agents with a favorable lipid-water partition coefficient and ionization constant. As such, many infectious processes warrant direct instillation of antibiotic at the site of infection (e.g., intracisternal, intrathecal, intra-articular). Additionally, cellular transporters (e.g., P-glycoprotein at the blood-brain barrier, organic anion and cation transporters at the choroid plexus) capable of pumping drug from the cell can limit distribution and retention of drug at the tissue level. The pH at the site of infection (e.g., in tissue fluids, exudates, transudates) relative to the pH in plasma also can govern distribution of a drug. For example, in cases of bacterial meningitis, the pH that occurs in the CNS is lower relative to plasma. Weak acids (e.g., penicillin) are more highly ionized in plasma than in cerebrospinal fluid (CSF) and pass more readily from the CSF into plasma than in the reverse direction. Similarly, when the pH of the local environment drops in the presence of infection, as occurs in lung abscesses, aminoglycoside efficacy is reduced because of chemical inactivation of the drug by ionization and the formation of stable adducts with high DNA concentrations found in purulent secretions. Finally, the physicochemical association of an intact (i.e., unmetabolized) drug with a particular physiologic fluid as part of its normal excretion profile can serve to localize drug at the site of infection (e.g., accumulation of drugs excreted by the biliary route in patients with cholangitis and in the urine in patients with nephritis). It is important to recognize that such interactions modify the activity of antimicrobial agents. For example, in vitro data demonstrate that daptomycin interacts with pulmonary surfactant, which in turn decreases the activity of the antibiotic. Hence the drug is not currently indicated in the treatment of pulmonary infections.[203] When drug-tissue and drug-body fluid interactions occur, different approaches including dose modification or combination therapy may need to be considered to optimize therapy.

PHARMACODYNAMIC DETERMINANTS OF EFFECT

The desired effect of any drug is realized when sufficient concentrations are achieved and maintained at the active site for an adequate period. In many models of disease for which the treatment targets of modern chemotherapy remain fixed, the concentration-effect (i.e., pharmacodynamic) relationships can be described with relatively modest effort. In contrast, evaluating the concentration-effect relationship for antimicrobial agents can be anything but straightforward, given the dynamic nature of infection. The intended target of the anti-infective agent is in constant flux as the number of organisms changes, the quantity and affinity of target receptors evolve, and the contribution of the host response adapts accordingly during the course of infection. Moreover, antimicrobial agents demonstrate variable effects at different concentrations and under different physicochemical environments. In fact, evaluating whether an organism survives

in the presence of antibiotic is only one criterion by which to predict or define drug effect. Rather, a variety of effects related to antimicrobial concentration—from the extremes of complete eradication to complete survival—can be observed in the invading organism. The previous sections of this chapter review the principles of pharmacokinetics, specifically, factors that link dose to concentration. The sections that follow include a discussion of the pharmacodynamics of anti-infective therapy and the multitude of factors that link concentration with effect.

Effects Described by Pharmacokinetic Parameters and Conventional Susceptibility End Points

Among the many decision-making tools that clinicians have at their disposal to guide in the selection of antimicrobial therapy are qualitative (e.g., breakpoints) and quantitative (e.g., MIC, minimal bactericidal concentration [MBC]) estimates of susceptibility. Although numerous studies and years of clinical evidence support the correlation between qualitative end points and clinical outcome, their predictive power is diminished in the presence of immunocompromise, severe underlying disease, mixed infections, and infection with organisms demonstrating heterogeneic resistance patterns.[30,37,58,140,149] Quantitative end points provide a better assessment of dose-effect relationships, with antibiotic concentration serving as a surrogate for the dose. However, these data alone do not reveal the complete picture relative to the anticipated bacterial response because laboratory-based quantitative tests contain a notable number of artificial aspects. Factors appreciated to influence the activity of antimicrobial agents in vivo (e.g., protein binding, fluctuating drug concentrations, serial drug exposure, inoculum size, immune defense status, physicochemical environment, compound stability) essentially are neglected when determining MIC values. As such, agents with comparable MIC values in vitro may, in fact, demonstrate markedly different effect profiles in a patient.[1,29,66,107,124]

In an attempt to move beyond reliance on quantitative tests as the sole marker for predicting antimicrobial activity in vivo, the integration of susceptibility information with population- and patient-specific pharmacokinetic data continues to be explored. Surrogate end points, defined by a combination of pharmacokinetic parameters and quantitative susceptibility data, have been suggested to predict more reliably the efficacy of different antimicrobial agents. By far, pharmacodynamic determinants of antimicrobial effect most frequently link attainable drug concentrations or estimates of total-body exposure, or both, with in vitro estimates of pathogen sensitivity. For antimicrobial agents for which the mechanism of action is determined to be time dependent (concentration independent), the percentage of time that plasma or tissue concentrations remain above the MIC has been closely linked to therapeutic response (Fig. 234-6). By comparison, the ratio of C_{max} to MIC has demonstrated a similar relationship for drugs with concentration-dependent killing (see Fig. 234-6). Furthermore, the ratio of AUC to MIC, which reflects the concentration profile over the course of time, has been used with both classes of agents (see Fig. 234-6).

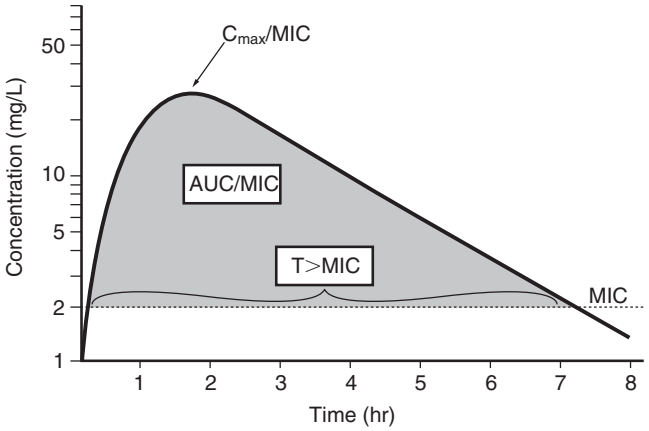

FIGURE 234-6 ■ Representative plasma concentration versus time curve illustrating commonly referenced pharmacodynamic parameters. AUC, area under the curve; C_{max}, maximal plasma concentration; MIC, minimal inhibitory concentration; T, time.

Evidence to support the application of specific pharmacodynamic surrogates is reviewed in the following paragraphs. However, a large degree of interdependence exists among these pharmacokinetic parameters. With few exceptions, when the dose of a drug is increased, C_{max} and the total AUC increase, and with no change in clearance, so, too, does the percentage of time that plasma drug concentrations remain above the MIC. Accordingly, making distinctions among the various pharmacokinetic parameters in an attempt to determine the optimal pharmacodynamic end point can be misleading. Given that many studies evaluate a limited number of doses or dosing intervals, restrict the number of pharmacokinetic parameters that are calculated, or neglect to perform multivariate analysis on the data, clear distinctions between parameters cannot always be made, and an appropriate degree of caution should be exercised when evaluating such data.[228]

Time Above the Minimal Inhibitory Concentration

Among the first class of antimicrobial agents to be discussed in the context of their concentration-effect relationships were the β-lactams, specifically penicillin. Although limited supporting evidence existed at the time, investigators were concerned with maintaining adequate blood levels of the drug in the host for a fixed period of time. This concern was reflected in their attempts to inhibit clearance pathways and formulate sustained-release preparations designed specifically for the purpose of extending the time spent above some minimal concentration (T > MIC).[17,186] As it turns out, in vitro studies support the relative concentration independence of penicillin and demonstrate that a maximal rate of killing can be observed that is quickly saturated at reasonably low multiples of the MIC (Fig. 234-7A). As concentrations increase above this maximal level,

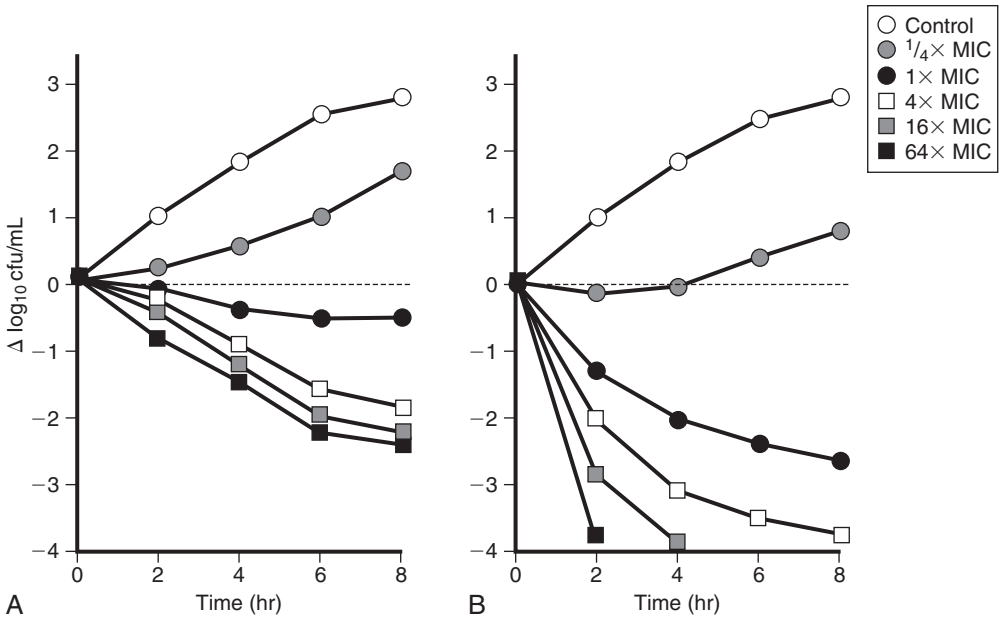

FIGURE 234-7 ■ Representative log-kill curves. These curves illustrate the response to concentration-independent **(A)** (time-dependent) and concentration-dependent **(B)** antimicrobial agents. MIC, minimal inhibitory concentration. (Modified from Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: a review. Scand J Infect Dis 1991;**74**[Suppl]:63-70.)

no faster rates of kill can be demonstrated.[34] Rather, penicillin displays time-dependent killing in which the duration of time spent above some minimal concentration (typically ±1 to 2 dilutions of the MIC or MBC) appears to be the most important determinant of activity.[49] As newer antimicrobial agents with putative time-dependent activity became available for evaluation, those with longer plasma and tissue terminal elimination half-lives demonstrated enhanced bactericidal activity when compared with similar drugs. Those that simply resulted in higher maximal peak concentrations, with no extension of the time above the MIC, produced minimal if any differences in effect.[10,83,193,235] This time-dependent activity has been observed in vitro with virtually all β-lactams (e.g., cephalosporins, carbapenems, monobactams) against both gram-positive and gram-negative organisms.[60,83,207,241] Similarly, other drug classes, namely, the macrolides, azalides, glycylcyclines, glycopeptides, ketolides, and oxazolidinones, appear to possess this same characteristic.[8,89,144,224,226]

When evaluating whether the time-dependent activity observed in vitro can be reproduced in vivo by evaluating intrinsic antibiotic activity in the host (through restriction of observations to animals in which the element of both humoral and cell-mediated immunity has been removed), the strongest relationship between antimicrobial concentration and effect for the aforementioned agents remains the time spent above the MIC.[187] Elegant studies evaluating extensive numbers of dosing regimens and drug-microbe combinations demonstrated that β-lactam and macrolide efficacy correlates best with the percentage of time spent above the MIC, irrespective of whether gram-positive or gram-negative pathogens are involved.[228] Given the same total daily dose, therapy administered at more frequent intervals is required for a successful outcome.[12,132] Even when the drug-microbe interaction is such that only bacteriostatic activity results, a regimen consisting of more frequent doses is able to maintain an environment of no net growth, whereas positive net growth is observed with larger doses administered less frequently.[75] From such data, the efficacy of time-dependent agents appears to be maximized by maintaining antibiotic concentrations above the MIC for as much of the dosing interval as possible.

When evaluating whether these agents obey the same relationship in the presence of a competent immune system, animal models similarly demonstrate a significant correlation between antimicrobial efficacy and the percentage of time spent above the MIC.[2,67] In contrast to immunocompromised animals, animals with a functional immune system do not require that virtually 100 percent of the dosing interval be spent above the MIC to achieve adequate antimicrobial activity. Although the bactericidal activity of penicillin ceases when concentrations fall below the MIC, the remaining organisms do not resume multiplication for many hours, well in excess of the time observed for the same organisms in vitro.[51,108] This difference may reflect the time required for the organism to recover from the initial antibiotic insult, coupled with the complementary activity of subinhibitory antibiotic concentrations and the immune system (these pharmacodynamic principles are explored later in further detail).[72] Irrespective of the mechanism by which the protracted antimicrobial effect occurs, the pharmacodynamic goals for time-dependent agents are not as stringent in vivo as they are in vitro. However, the persistent suppression of bacterial growth is not indefinite, and a maximal amount of time can be spent below the MIC before a reduction in efficacy becomes apparent. Thus, a maximal dosing interval for these agents appears to exist in immunocompetent hosts, beyond which a decrease in efficacy can be expected.[50,198]

Clinical studies further confirm that for the agents discussed earlier, time above the MIC is a suitable pharmacodynamic end point in patients. In clinical studies of upper respiratory tract infection, the highest bacterial eradication rates for the β-lactams are observed when the time above the MIC exceeds 40 to 50 percent of the dosing interval.[38] For cefuroxime, cure rates drop from greater than 90 percent to approximately 75 percent when the time above the MIC falls to less than 40 percent.[70,79] Patients infected with a susceptible organism show 92 percent efficacy with a continuous-infusion regimen of cefamandole versus 63 percent efficacy with intermittent administration of the agent. Finally, in neutropenic patients, an overall efficacy rate of 65 percent was observed after continuous infusion of cefamandole as opposed to 21 percent efficacy in patients receiving intermittent administration.[24] For macrolide-susceptible pathogens, cure rates approaching 100 percent were observed when concentrations remained above the MIC for greater than 80 percent of the dosing interval.[38] As the MIC increases such that the percentage of time spent above the MIC falls, so too do cure rates. Macrolide concentrations rarely exceed the MIC for *Haemophilus influenzae*, and cure rates are comparable to those seen in placebo-treated individuals.[38] A few studies appear to contradict the aforementioned data, findings indicating that little difference in clinical response is observed when the same total daily dose of selected agents is administered as a continuous infusion or with increased frequency versus less frequent intermittent administration; however, a prolonged postantibiotic effect (PAE) or protracted half-life, such that both of the regimens evaluated spend nearly 100 percent of the dosing interval above the MIC, may explain these discrepancies.[28,127,229]

A natural extension of the considerations just discussed relates to the utility of continuous infusions for antimicrobial agents that exhibit time-dependent killing, a topic that has historically been controversial. Theoretically, continuous drug administration would ensure that serum concentrations and potentially those at the site of action would never fall below the MIC. This would be of particular value for antimicrobial agents with a short half-life, in patients in whom drug exposure is limited based on increased volumes of distribution or clearance rates, and in patients who have a significant degree of immunocompromise. Although the benefits appear obvious, the clinical findings are equivocal, with data both supporting and refuting improvement in clinical outcomes related to continuous antimicrobial administration. Variability in antibiotic dosing, disease severity, causative bacterial pathogens, and susceptibility patterns all add to the complexity of accurately assessing prolonged infusions.[185] Moreover, challenges encountered with the administration of a continuous infusions of antimicrobial agents include obtaining adequate serum concentrations, drug stability, practicality of administration, and potential adverse reactions associated with prolonged drug exposure. Consequently, clinical guidelines for the application of continuous infusions are lacking and additional data are needed to better understand the potential advantages and disadvantages of continuous infusions, particularly in the setting of more highly resistant pathogens and in complex pediatric patient populations.

Concentration Above the Minimal Inhibitory Concentration

In contrast to the aforementioned agents, a smaller group of agents demonstrate concentration dependence, with the magnitude of antimicrobial effect increasing in direct proportion to increasing drug concentrations (see Fig. 234-7B).[16,146] The aminoglycoside and fluoroquinolone antibiotics are the prototypic drugs of this pharmacodynamic class; however, concentration-dependent activity also has been observed with the lipopeptides, metronidazole and the echinocandins.* Unlike the time-dependent agents, for which shortening the dosing interval results in increased efficacy, extending the dosing interval for concentration-dependent drugs affords an ability to increase the dose and results in a greater reduction in bacterial inoculum and, for some agents, a diminution in adaptive resistance.[39] Although highly variable, optimal ratios of peak plasma concentration to MIC that result in complete killing have been defined for many drug-microbe combinations. Similarly, ratios of C_{max} to MIC (C_{max}/MIC) can be defined, below which the organism is afforded the opportunity to regrow with increased selection of resistant subpopulations.[22,45,46]

Concentration-dependent killing for many of these agents has been demonstrated in both animal models and human clinical trials. In neutropenic mice with pseudomonal soft tissue infection, dosing schemes that deliver larger aminoglycoside doses less frequently result in greater killing than do schemes with the same total daily dose administered more frequently, even though all regimens achieved serum concentrations in excess of the MIC.[75] In patients receiving quinolone therapy for the treatment of respiratory tract, urinary tract, and skin and soft tissue infections, several pharmacodynamic parameters proved to correlate with clinical response; however, the best correlation was observed with the C_{max}/MIC ratio.[174] In clinical trials in which patients received aminoglycoside therapy for gram-negative infections, the strongest association between pharmacokinetic indices and clinical response was observed with the C_{max}/MIC ratio. In fact, the relationship between the C_{max}/MIC ratio and clinical response appeared to be linear over the range of clinically relevant plasma concentrations. No significant difference occurred in the time to achieve C_{max} between responders and nonresponders; therefore, the improved response rates in patients achieving higher peak plasma concentrations were not simply an artifact of drug accumulation as a result of longer duration of therapy.[154,155]

In addition to the absolute peak plasma concentration, the time that optimal peak levels are achieved appears to play a critical role in the response to concentration-dependent antimicrobial agents. A significant correlation with clinical improvement and reduction in mortality is observed if therapeutic peak plasma concentrations are reached early during the course of treatment.[156,159] The

*References 5, 40, 143, 176, 206, 225.

probable reason for this effect is that the response of the bacterial population to the same antibiotic concentration can change with subsequent doses. As alluded to earlier, subtherapeutic peak plasma concentrations serve to select out fewer susceptible variants within the population.[22,23,74] Based on these data, a key goal of therapy (i.e., in addition to proper drug selection) for concentration-dependent agents appears to be the attainment of high peak plasma concentrations early in therapy to afford rapid initial killing and minimize adaptive resistance.

Although prolonging the dosing interval affords the luxury of increasing the dose to optimize killing, the law of diminishing returns applies even for concentration-dependent agents, and it is possible to increase the dosing interval to excess and decrease efficacy. Despite the clear concentration dependence with escalating doses of fluoroquinolones, a simulated every-12-hour regimen was less effective than was a regimen using the same total daily dose administered every 8 hours.[15] Similarly, animal models of gram-negative lung and soft tissue infection suggest that delayed clearance of the infecting organism is observed in response to aminoglycoside and fluoroquinolone therapy when administered in protracted dosing regimens (e.g., dosing interval much greater than the half-life) as opposed to shorter dosing intervals.[132,158,187] Again, scattered studies appear to contradict these findings; however, they use agents with a longer half-life and therefore the dosing interval may, in fact, not exceed the time spent above the MIC plus the residual PAE.[43] Thus, despite their concentration dependence, an element of time appears to be involved in the response to these agents. Unless peak concentrations are achieved in excess of those necessary to obtain maximal kill rates and the dosing interval does not markedly exceed time above the MIC plus the PAE, the efficacy of such agents is not only dose dependent but also dose interval dependent.

Total-Body Exposure Above the Minimal Inhibitory Concentration

The AUC, a reflection of total-body exposure, is a pharmacokinetic parameter that integrates both time and drug concentration. Estimates of AUC reflect the magnitude of the dose received and the drug half-life relative to the dosing interval. Accordingly, researchers have proposed that the ratio of AUC to MIC (AUC/MIC ratio) may serve as a better surrogate of pharmacodynamic activity for both time- and concentration-dependent agents. In several studies, the AUC/MIC ratio serves as the best correlate of the reduction in number of organisms for aminoglycosides, quinolones, streptogramins, rifamycins, isoniazid, evernimicin, echinocandins, and azole antifungal agents.* Because of the interdependence between AUC and the pharmacokinetic parameters previously noted, studies also can be identified that demonstrate a relationship between clinical or microbiologic outcome and the AUC/MIC ratio for agents with time-dependent activity (e.g., the β- lactams and glycopeptides). Often, however, these studies fail to evaluate multiple pharmacokinetic parameters.[153,197]

**References 4-7, 44, 55, 109, 110, 168.

In an elegant study evaluating certain aminoglycoside dosing regimens against *Pseudomonas aeruginosa* and *Escherichia coli* infection, the log-normalized AUC provided the best correlation with efficacy. However, as was observed with concentration-dependent agents, when the dosing interval exceeded the time above the MIC plus the residual PAE, the best correlation with efficacy was the percentage of time spent above the MIC, thus reaffirming that the dosing interval can be too long with the aminoglycosides.[228] A meta-analysis of 19 studies evaluating eight quinolones and six different organisms in experimental endocarditis similarly demonstrated a correlation between the AUC/MIC and reduction in $\log_{10}$ colony-forming units (CFUs) per vegetation. However, given the relationship between the pharmacokinetic parameters, C_{max}/MIC and time greater than MIC also proved to correlate with a decrease in the size of the inoculum.[3] In human investigations, AUC/MIC appears to serve as the best predictor of clinical response, microbiologic response, and bacterial eradication for the fluoroquinolones. Nonetheless, C_{max}/MIC and time greater than MIC can be linked similarly to bacterial eradication for this class of agents.[63,64,170]

Clearly, the optimal AUC/MIC ratio will be different for different organisms despite sharing a similar quantitative susceptibility end point. Similarly, optimal AUC/MIC ratios are highly variable and depend on the antimicrobial agent being evaluated. For example, effective eradication of organisms implicated in nosocomial pneumonia is observed with an AUC/MIC ratio of 540 for cefmenoxime, 34 for tobramycin, and 23 for ciprofloxacin.[196] Consequently, attempts have been made to standardize this pharmacodynamic end point, and investigators have proposed a value of 125 as the cutoff below which a reduction in efficacy and increase in resistance may be expected.[100,195] However, optimal AUC/MIC ratios may differ, depending not only on a given organism and agent but also on the desired outcome and the disease state. A ratio greater than 125 resulted in bacterial eradication roughly 7 days after the initiation of β-lactam and quinolone therapy; however, an AUC/MIC ratio of 250 resulted in eradication of the pathogen within 1 to 2 days after initiating quinolone therapy.[195] For patients with acute exacerbations of chronic bronchitis who are receiving fluoroquinolones, an AUC/MIC ratio less than 276 was associated with longer time to clinical success, whereas a ratio greater than 576 was associated with a reduction in coughs per day and a ratio greater than 212 with decreasing days to a reduction in the volume of sputum.[151] In an animal model of bacterial endocarditis, significantly lower numbers of organism were found in the vegetation after 3 to 6 days of therapy when the AUC/MIC ratio exceeded 100.[3] Moreover, a value of 100 appeared to be the cutoff below which an increased risk of resistance was observed in a retrospective review of 107 acutely ill patients with lower respiratory tract infection.[218] Furthermore, in vitro models evaluating fluoroquinolone activity against *Streptococcus pneumoniae* demonstrated effective eradication with an AUC/MIC ratio between 30 and 65, much lower than the value of 125 reported as optimal for other pathogens.[126,136]

Although this hybrid parameter bridges concentration and time (i.e., extent of systemic drug exposure from a given dose) and has been demonstrated to correlate with efficacy for numerous drug classes, optimal criteria appear to vary with the organism, agent, disease state, and desired outcome. In addition, established relationships no longer may hold for some agents when a protracted dosing interval is used in therapy. As such, a general classification and standard outcome are not straightforward, and agents need to be evaluated with respect to known mechanisms of activity and the specific clinical and microbiologic situations in which they are used.

Optimal Surrogates for Drugs in Combination

Combination antimicrobial therapy is initiated in numerous circumstances: to ensure broad-spectrum coverage early in therapy, to treat polymicrobial infections, and to combat organisms that require multiple agents for effective eradication. Often, combination therapy entails the use of agents from different classes or agents that have different mechanisms of action (or both). This particular situation raises the question of how one applies the aforementioned pharmacodynamic principles to selecting or evaluating the efficacy of drug therapy when confronted with the combined use of agents that do not share similar pharmacodynamic targets. Although optimization of combination therapy may be possible by choosing the interval for one agent,[76] efficacy appears to be explained best when a combination of both pharmacodynamic properties is considered.[75,157]

Reasonable models of a concentration-effect relationship have been proposed for numerous agents alone and in combination; however, optimal ratios remain to be defined for many drug-microbe combinations. Moreover, it is probably more complex than simply defining the optimal ratio for specific combinations. Even though one can define the best correlate, killing rates, in fact, may vary with the site of infection because penetration of a drug into or clearance from tissue varies from site to site. For example, logAUC proves to be the best predictor for clearance of organisms from the lung regardless of the dosing interval used. In contrast, given faster drug clearance from the thigh, the time above the MIC was a more important predictor of eradication when a longer dosing interval was used, whereas the logAUC was the best predictor of clearance of organisms with the use of shorter dosing intervals.[133] Similarly, in animal models of bacterial meningitis, greater kill rates were observed as time greater than MBC increased. However, when concentrations remained above the MBC for the entire dosing interval, which may not be unexpected in situations in which the antibiotic half-life is longer in CSF than in plasma, kill rates were directly proportional to both peak/MBC and AUC/MBC ratios.[145] These data suggest that we may need to expand the characterization of pharmacodynamic surrogates to look at the pharmacokinetic-pharmacodynamic interface at the site of infection rather than simply defining dosing strategies based on in vitro susceptibility data and the disposition characteristics of drugs in plasma. Without question, many data need to be collected and verified in the human host. The maximal dose and dosing regimen ideally are selected so that the resultant pharmacokinetic profile affords optimal pharmacodynamic activity without causing unnecessary adverse events, therapeutic failure, or both, as may be observed with inappropriate dosing. Development of a successful therapeutic strategy requires the following: incorporation of knowledge regarding the infecting pathogen; the physicochemical, pharmacologic, and pharmacokinetic properties of the anti-infective agent; and specific factors of the host or disease that are capable of altering either drug disposition or action. Such an approach enables the clinician to make clearer distinctions among agents with similar susceptibility profiles yet different mechanistic or pharmacokinetic profiles and to select an optimal drug regimen that will be most likely to result in successful therapy.

Effect of Suprainhibitory Antimicrobial Concentrations (Eagle Effect, Paradoxical Zone Phenomenon, Concentration Quenching)

In simplest terms, one typically thinks that anti-infective activity increases with increasing antimicrobial concentration. More sophisticated models describe increasing activity with increasing drug concentration to a maximal effect until activity reaches a plateau and remains relatively constant despite further increases in drug concentration (see Fig. 234-7). However, for many antibiotics, an increase in drug concentration can, in fact, result in a reduction in antimicrobial activity (Fig. 234-8).[96] This paradoxical effect was observed as early as 1945 and described 3 years later by Eagle and Musselman, who reported the existence of antibiotic concentrations above the maximally effective concentration at which the killing rate of bacteria is paradoxically reduced.[52,122] This phenomenon has been described with a host of organisms and although originally observed with penicillin has been

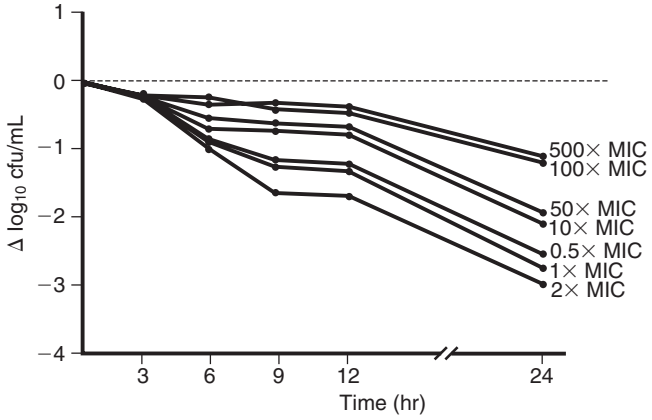

FIGURE 234-8 ■ Representative log-kill curve demonstrating the paradoxical effects that can be observed with suprainhibitory antimicrobial concentrations. MIC, minimal inhibitory concentration. (Modified from Holm SE, Odenholdt-Tornqvist I, Cars O. Paradoxical effects of antibiotics. *Scand J Infect Dis Suppl* 1991; **74**:113-7.)

confirmed with other β-lactams, glycopeptides, aminoglycosides, and fluoroquinolones.[142,161,171,213,238] Given the diversity of agents that demonstrate a paradoxical reduction in activity with increasing drug concentration, this phenomenon probably cannot be explained by a single mechanism; and although they are not definitively elucidated, numerous mechanisms have been proposed to explain these observations.

For certain β-lactam antimicrobials, induction of β-lactamase may be responsible for the paradoxical effects observed in selected organisms. In vitro experiments performed with *Proteus vulgaris* suggested that the greatest paradoxical response seen with β-lactams was observed with agents that demonstrated the highest β-lactamase–inducing capacity and the poorest stability to degradation by this enzyme. When a mutant strain of this organism that was unable to induce β-lactamase production was evaluated, no paradoxical effect was noted.[104] In animal models of peritoneal infection, antibiotics with strong dose-dependent induction of β-lactamase similarly demonstrated a paradoxical effect against β-lactamase–positive strains of *P. vulgaris.* However, no paradoxical effect was observed against β-lactamase–negative strains. Agents that were only weak inducers of β-lactamase demonstrated no evidence of a paradoxical effect, regardless of whether the *P. vulgaris* strains produced β-lactamase.[102]

Because this paradoxical effect can be demonstrated with the β-lactams against organisms that do not produce β-lactamase, other mechanisms must also be responsible. One such mechanism may involve dysregulation of the bacterial autolytic system, which often confers tolerance to an organism but also may uncover an Eagle-type effect.[91] A paradoxical reduction in antimicrobial activity at high doses may be related to differences in regulation or expression of these autolytic enzymes. In *Enterococcus* strains that fully express only one of two recognized autolytic enzymes, diminished or deficient production of the second enzyme resulted in a paradoxical response to penicillin. Strains in which both enzymes were produced remained susceptible to the antibiotic irrespective of concentration, thus suggesting that a proportional dose-response relationship may require the synergistic activity of both enzymes.[61,62] Further investigation into the paradoxical effect observed in tolerant organisms suggests that organisms in the exponential growth phase demonstrate this response more consistently than do those in the stationary phase.[172,175] Animal models of *Staphylococcus aureus* endocarditis provide in vivo confirmation of the paradoxical response observed with tolerant organisms in vitro. Administration of continuous-infusion cloxacillin to animals infected with a nontolerant strain produced a dose-proportional reduction in bacterial density (log_{10}CFUs/g) within the vegetation, whereas animals infected with a tolerant strain demonstrated a reduction and subsequent paradoxical increase in bacterial density with increasing dose. No statistical difference was observed in bacterial density within other organs or in overall survival, which raises questions regarding the in vivo significance of these observations.[230]

For antibiotics that demonstrate polyfunctional activity at supratherapeutic concentrations, a paradoxical response may occur as a result of secondary alterations in cellular functions that are requisite for antimicrobial activity. Despite a principal mechanism of action for the fluoroquinolones at the site of DNA gyrase, these agents appear to be bactericidal only in cells able to synthesize protein. As quinolone concentrations increase above those that are bactericidal, RNA synthesis and therefore protein synthesis are progressively inhibited, thus explaining the reduced rate of bactericidal activity observed at high quinolone concentrations.[184] Incompletely characterized genetic modifications also may confer a paradoxical response to antibiotics. β-Lactam resistance in methicillin-resistant *S. aureus* (MRSA) is mediated by derepressing the production of a low-affinity PBP. However, because the modified PBP serves as an inefficient transpeptidase, it is regarded as an internal selective pressure in the bacterium, and a countermutation has arisen. Although it is not completely understood, the phenotypic expression of this countermutation is manifested as an Eagle-type resistance to methicillin.[123,192] Finally, an observed paradoxical response may not be a result of the drug-microbe combination alone but a result of the chemical environment as well. A paradoxical effect with penicillin, in which both cell count and the rate of killing were affected, was demonstrated in *Streptococcus agalactiae* when the pH was reduced under in vitro conditions.[103]

Most studies investigating the Eagle effect have been conducted in vitro, and the clinical implications of the paradoxical phenomenon have yet to be fully elucidated. However, anecdotal evidence appears to suggest that the clinical efficacy of antimicrobial agents can be compromised by high-dose antibiotic therapy. Case reports of β-lactam–susceptible streptococcal endocarditis and staphylococcal pneumonia describe patients who failed to respond to high-dose β-lactam therapy (plasma concentrations >100 times the MIC in one case), with subsequent improvement in each case when the dose was lowered.[73,84,216] For many agents, it is clearly advantageous to establish high peak drug concentrations early, the benefits of which include increasing log kill, preventing the selection of resistant mutants, overcoming refractoriness, and enhancing penetration of tissue. However, the relative safety of many drug classes (e.g., the β-lactams) often results in the use of doses that may be higher than necessary. When clear evidence is lacking for enhanced bactericidal activity at higher concentrations and the potential for diminished efficacy exists, escalation of antibiotic doses should be considered judiciously.

Effects of Subinhibitory Antimicrobial Concentration

Individuals may be exposed to subtherapeutic antimicrobial concentrations for many reasons, including underdosing, poor compliance, and, perhaps most commonly, the inability of the pharmacokinetic profile of the agent in question to afford adequate penetration to the site of infection. Exposure of bacteria to antibiotic concentrations below the MIC can have variable effects, depending on the organism and the antimicrobial agent. In fact, the

effects observed with subinhibitory levels are not simply a milder extension of those observed at inhibitory concentrations but, instead, are qualitatively different from the effects observed at concentrations that equal or exceed the MIC.[138] Subinhibitory concentrations can have the following effects: enhance or impair opsonization and phagocytosis; affect the virulence of the bacteria by modifying the bacterial cell surface; alter adherence properties, antigen expression, or the excretion of enzymes and toxins (or any combination of these effects); and inhibit bacterial growth.[163,164,221] The result can be an increase or decrease in responsiveness to therapy, both of which are discussed later in this section. Before reviewing the current data, however, one should note that this discussion does not refer to subinhibitory concentrations occurring after initial suprainhibitory drug levels. These particular effects are distinguished as PAE and are addressed separately.

Even though antibiotic concentrations may fail to reach or exceed the MIC, these agents still can affect the growth of an invading organism adversely.[138,139,141] In fact, the term *minimal antibacterial concentration* (MAC), usually a fraction of the MIC, was coined to describe the lowest concentration of antibiotic required to produce either structural changes in the bacterium, a 1 $\log_{10}$ decrease in the number of organisms present, or a 10 percent delay in turbidimetric growth in vitro.[71,212] Rather than resulting in treatment failure, subinhibitory antimicrobial concentrations in concert with defenses in an immunocompetent host may be sufficient to clear the infection.[221] Many effects have been observed to occur as a result of exposure to subinhibitory antimicrobial concentrations, and they are mediated by a variable number of mechanisms.

Increased susceptibility to phagocytosis may be seen with subinhibitory antibiotic concentrations and can occur in many ways. Subinhibitory concentrations may induce morphologic changes in the bacterium such that its size and shape are altered markedly, and, as a result, the immune system is signaled to clear the bacterium.[11,212,231] However, subinhibitory concentrations of drugs that share a common intracellular target cannot be expected to have the same effects on bacterial morphology. Even though both penicillins and cephalosporins act through PBPs, subinhibitory concentrations of penicillins induce filaments in *Proteus mirabilis*, whereas cephalosporins induce the formation of globules.[139,141,216] A likely explanation lies in their different affinity for the various PBPs, whereby they can be expected to bind selectively at low concentrations and rather nonspecifically at therapeutic or supratherapeutic concentrations. The preferential binding of ceftibuten to PBP-3 of *E. coli* at subinhibitory concentrations results in filamentation because this PBP allows crosswall but not sidewall synthesis.[26] Similarly, subinhibitory concentrations of the same drug applied to different organisms can produce different morphologic changes. In *S. aureus*, subinhibitory concentrations of loracarbef induce no morphologic changes, whereas similar concentrations lead to elongated forms and short-chain forms in *E. coli* and elongated and filamentous forms in *H. influenzae*.[222]

Although size may be one factor stimulating enhanced clearance of the organism, increased uptake by the immune system can be demonstrated even for cells with little gross morphologic alteration. Subinhibitory antibiotic concentrations can impair the synthesis of antiphagocytic surface factors or liberate their release, thereby enhancing complement binding, opsonization, phagocytosis, and, ultimately, bacterial killing.[93,98,128] Production of the antiphagocytic A protein of *S. aureus* can be repressed by subinhibitory concentrations of selected protein synthesis inhibitors and fluoroquinolones.[148,205] Subinhibitory concentrations of β-lactam agents, but not vancomycin or protein synthesis inhibitors, increase the susceptibility of *S. agalactiae* to uptake by polymorphonuclear leukocytes (PMNs) because of the loss of antiphagocytic capsular material.[97] Carbapenems and cephalosporins at subinhibitory concentrations increase the serum sensitivity of K1-positive *E. coli* by reducing expression of the K1 capsular polysaccharide.[214]

Even drugs with no inherent bacteriostatic or bactericidal activity against a specific organism can induce sufficient changes in the cell surface to affect serum sensitivity. Pre-incubation of *P. aeruginosa* with subinhibitory concentrations of certain macrolides decreases cell surface hydrophobicity and enhances the sensitivity of the organism to human serum bactericidal activity.[217] Subinhibitory β-lactam concentrations are capable of sufficiently altering the peptidoglycan structure in MRSA to enhance susceptibility of the organism to the lysozyme present in sputum, even though the organism, because of altered PBP production, is no longer susceptible to the bactericidal activity of these agents.[101] Although most effects stimulating bacterial clearance by the host occur as a direct result of cellular changes in the organism, immune cells also can be altered by subinhibitory antibiotic concentrations. Erythromycin does not affect the generation of serum-derived leuko-attractants, nor does it increase PMN cell numbers, yet it appears capable of stimulating the migration of PMNs. Researchers suggested that this effect probably results from the ability of erythromycin to sustain cellular migration by reducing the level of leuko-attractant–induced auto-oxidation mediated by the myeloperoxidase–hydrogen peroxide–halide system.[57]

In addition to enhancing bacterial clearance, subinhibitory antibiotic concentrations also can impair bacterial virulence mechanisms. For many organisms, pili, fimbriae, and fimbriae-associated adhesins are responsible for the initial events surrounding adherence and colonization at the site of entry or infection.[194] Subinhibitory quinolone and clindamycin concentrations are capable of decreasing the adherence of nosocomial pathogens (e.g., *Staphylococcus epidermidis)* to the synthetic materials of implantable catheters.[31,202] Subinhibitory concentrations of penicillins, cephalosporins, azalides, and quinolones all have demonstrated the ability to decrease the formation of fimbriae or alter structures that mediate adherence. Specific examples include decreased adherence to oral and urinary tract epithelial cells for organisms such as *Porphyromonas gingivalis*, *E. coli*, *Salmonella typhimurium*, and *P. aeruginosa*.[26,137,205,215,231] Moreover, these effects do

not appear to be growth phase–specific for select drug-microbe combinations.[27]

Subtherapeutic antibiotic concentrations also can have an impact on virulence by downregulating bacterial toxin production. Subinhibitory concentrations of clindamycin can inhibit toxin production in *S. epidermidis* markedly without appreciably altering bacterial growth.[202] *Pseudomonas* exoenzymes that facilitate disease pathogenesis (e.g., exotoxin A, exoenzyme S, phospholipase C, total protease, elastase) are suppressed after exposure to subinhibitory concentrations of ciprofloxacin, tobramycin, and ceftazidime.[85] Finally, given the ability of subinhibitory fluoroquinolone concentrations to disrupt DNA structure sufficiently to interfere with effective mRNA production, continuous exposure of *S. aureus* to fluoroquinolones at subinhibitory concentrations decreases the production of nuclease and hemolytic α-toxin production.[205]

Although discerning which of these effects, alone or in combination, are responsible for the subinhibitory effects is difficult, one may see in vivo that the impact of the sum total of these effects can be observed at the level of the host. In a non-neutropenic rat model of *Klebsiella pneumoniae* pneumonia, a continuous infusion of ceftazidime resulting in steady-state concentrations of 0.06 mg/L protected all the animals from death, despite an MIC for the pathogen of 0.2 mg/L. The same could not be said, however, for immunocompromised animals, which required steady-state concentrations of 0.38 mg/L for adequate protection.[188,189] In a similar model of intraperitoneal *K. pneumoniae* infection, subinhibitory clindamycin concentrations resulted in an increase in bacterial clearance and a decrease in the $\log_{10}$CFUs in blood at 72 hours.[9] In humans, low-dose ampicillin (such that concentrations in urine were no greater than one-fourth to one-half times the MIC) combined with large water intake was demonstrated to clear documented *E. coli* urinary tract infection in 16 of 20 patients within 2 days of initiating therapy, whereas none of the 18 control subjects receiving the fluid intervention alone demonstrated resolution of the infection.[181] Despite the resistance of *Pseudomonas* in patients with cystic fibrosis, the fluoroquinolones remain capable of eliciting a significant reduction in sputum colony counts and improvement in clinical signs and symptoms.[200,204]

Subinhibitory antimicrobial concentrations can be as potentially disadvantageous to the host as they can be beneficial. These concentrations can impair the ability of the host to respond to the bacterial inoculum, can augment bacterial defenses, and can serve to inactivate the antibiotic. For organisms that are susceptible to β-lactamase induction, strong inducers can upregulate β-lactamase synthesis at concentrations below the MIC. Although β-lactamase induction typically is a reversible phenomenon, many antibiotics demonstrate the ability to select out genetically de-repressed mutants at subinhibitory concentrations.[201,209] Irrespective of whether this induction is phenotypic or genotypic, many antibiotics to which the organism originally may have been susceptible no longer retain their efficacy in light of β-lactamase production. This type of adaptive resistance, observed in response to sublethal antibiotic concentrations, also can be nonenzymatic. A single, one-time exposure of *P. aeruginosa* to subinhibitory concentrations of chlorhexidine results in unstable resistance, and repeated exposure leads to stable expression of altered cell surface macromolecules or efflux systems responsible for resistance.[219] In a clinical strain of this same organism exposed to subinhibitory concentrations of fluoroquinolones and carbapenems for 5 days, a 16- to 32-fold increase in MIC was observed in concert with an alteration in overall protein expression.[32]

Sublethal antibiotic concentrations also can stimulate the production of toxins that may be detrimental to the host. Exposure of enterohemorrhagic *E. coli* to subinhibitory concentrations of fluoroquinolones, cephalosporins, tetracyclines, and inhibitors of folic acid synthesis induces enhanced expression of a *Shiga*-like toxin (SLT-1), which is proposed to mediate events surrounding the development of hemolytic-uremic syndrome. Subinhibitory fluoroquinolone concentrations also can stimulate the production of verotoxins in this same organism.[232,239] Lincomycin and tetracycline at subinhibitory concentrations stimulate the production of heat-labile enterotoxin in enterotoxigenic *E. coli*, as well as *Vibrio cholerae* enterotoxin, even though these agents are principally protein synthesis inhibitors. Prior data suggest that the copy number of plasmids does not increase and proposed that the rate of enterotoxin liberation is enhanced as a result of antibiotic inhibition of the synthesis of proteins responsible for degrading the toxin.[135,240] The α-toxin of *S. aureus* is demonstrated to be hemolytic, dermonecrotic, and antichemotactic and appears to be upregulated in the presence of subinhibitory nafcillin concentrations, irrespective of whether the isolate is susceptible to the agent. Greater hemolytic activity and increased lethality of the broth filtrate in a murine intraperitoneal model are observed, and this activity is ablated when incubated with anti–α-toxin antibody.[120] Other β-lactams (with the exception of aztreonam), ofloxacin, and trimethoprim are similarly capable of inducing α-toxin expression at subinhibitory concentrations.[165]

The upregulation of protein expression by subinhibitory antibiotic concentrations not only is responsible for contributing to antibiotic and cellular destruction but also can enhance the binding of pathogens to host proteins and implantable devices. Subinhibitory concentrations of ciprofloxacin increase the transcription of fibronectin-binding proteins in *S. aureus* isolates and thereby result in greater adhesion to immobilized fibronectin and fibronectin-coated polymers, a particular concern with subcutaneously implanted devices that have polymer surfaces.[19,20] Subinhibitory concentrations of antibiotic also can alter the immunogenicity of the pathogen such that the host can no longer mount the same degree of immune response. *S. aureus* isolates coincubated with subinhibitory concentrations of oxacillin demonstrated a diminished capacity to stimulate proinflammatory cytokine production (e.g., tumor necrosis factor-α, interleukin [IL]-1β, and IL-6) in human monocytes. Given that activation of the complement system and cytokine release are stimulated by peptidoglycan

molecules of a certain size or tertiary structure, subinhibitory β-lactam concentrations probably distort the peptidoglycan structure sufficiently that the immune system no longer effectively responds to these immunostimulatory components.[199]

Unless unusual circumstances prevail, the goal of therapy probably will not be to target plasma concentrations below the MIC. However, given the reality of encountering this situation in the clinical setting, practitioners certainly need to be aware of the potential implications for therapeutic response associated with subinhibitory concentrations of antimicrobial agents.

Effects That Persist After Antimicrobial Exposure (Postantibiotic Effect, Postantibiotic Leukocyte Enhancement, and Post–β-Lactamase Inhibitor Effect)

Early investigations into antibiotic activity described a delay in the recovery and regrowth of penicillin-exposed staphylococci and streptococci when the drug was removed by enzymatic inactivation or the organism was removed to drug-free media.[18,48,169] In addition, in vivo evaluations of penicillin activity suggested that the effects of penicillin in an immunocompetent animal lasted well beyond the time when blood levels remained above quantifiable concentrations. Despite a half-life of minutes, many hours could elapse after the administration of a dose of penicillin before bacterial growth resumes.[51,108,198] The term *postantibiotic effect* was coined to describe the suppression of bacterial growth that persists after brief exposure of the organism to an antimicrobial agent.[36] Unlike the subinhibitory effects discussed earlier in the chapter, the PAE occurs as a result of residual antimicrobial activity after initial exposure at inhibitory concentrations, as opposed to the subinhibitory concentrations themselves. The PAEs described to date typically are reversible; and although the mechanisms have not been elucidated fully, they probably are caused by either nonlethal damage or persistence of antibiotic at the site of action. In the same vein as the PAEs, the term *post–β-lactamase inhibitor effect* (PLIE) was coined to describe the residual effects of β-lactamase inhibitors after exposure to inhibitory concentrations.[220] Similarly, one encounters the term *postantibiotic leukocyte enhancement* (PALE), which is used to account for a PAE in vivo that lasts longer than that observed in vitro and is defined as exposure to subinhibitory concentrations of an antibiotic that render the organism more susceptible to the phagocytic and bactericidal action of neutrophils.

The PAE depends on many factors, the most discernible being the drug-microbe combination.[106] Since the initial descriptions with penicillin were reported, similar observations have been noted for a broad range of organisms, and essentially all antibiotic classes demonstrate a PAE against select organisms.[36] Virtually all agents evaluated demonstrate a PAE against susceptible gram-positive cocci. Inhibitors of protein and nucleic acid synthesis produce longer-lasting PAEs in vitro than do cell wall–acting agents, with an average of 1 to 2 hours for β-lactams, 1 to 3 hours for fluoroquinolones, and 3 to 5 hours for protein synthesis inhibitors. For resistant gram-positive cocci, descriptions of a PAE are mixed. Against gram-negative bacilli, no appreciable PAE is observed for trimethoprim or the β-lactams in vitro, with the exception of the carbapenems, which demonstrate a PAE of 1 to 2 hours. The fluoroquinolones and protein synthesis inhibitors have PAEs of roughly 1 to 3 hours and 3 to 8 hours, respectively. Within this group of organisms, *P. aeruginosa* serves as an exception and the fluoroquinolones and protein synthesis inhibitors display slightly shorter PAEs—1 to 2 hours and 2 to 3 hours on average for the respective drug classes. Similar observations have been described for the gram-negative anaerobes, with little or no PAE seen with the β-lactams but a measurable PAE observed for protein synthesis inhibitors.[36]

Given that most drug classes demonstrate a PAE, multiple mechanisms must exist by which this effect arises. For the β-lactams, researchers proposed that the PAE corresponds to the time required for the organism to synthesize new PBPs. The initial high β-lactam concentrations are thought to bind irreversibly to and thus inactivate the PBPs. As such, cell multiplication subsequently is prolonged until a critical number of PBPs are resynthesized and cell division can resume.[221] Within the large class of β-lactam agents, however, further distinctions can be made based on the specific PBP bound and the subsequent morphologic alteration that is induced. Against *E. coli*, the longest-lasting PAEs are observed for agents that induce the formation of spheroplasts and the shortest for agents that induce the formation of filaments. On drug removal, filaments (which may contain a biomass corresponding to more than 20 bacteria) readily separate into individual bacteria, whereas spheroplasts require a longer period to resynthesize a normal cell wall and resume replication.[90] Analogous to the β-lactams, the time required for the resynthesis or recovery of ribosomal proteins is probably responsible for the PAEs observed after the administration of an aminoglycoside. Evaluation of the intracellular events taking place in *E. coli* during aminoglycoside-induced PAEs suggests that both DNA and RNA synthesis resume immediately after drug removal; however, synthesis of structural and functional protein does not resume for nearly 5 hours.[13,106] For the fluoroquinolones, the proposed mechanism behind the PAE is not as consistent with the antimicrobial activity of these agents. A progressive increase in ^{3}H-thymidine incorporation in *S. aureus* during the PAE suggests that DNA synthesis continues to occur, and, thus, the PAE may represent the time needed to repair the damage to DNA gyrase, the time required to reestablish the function of DNA gyrase after dissociation of the antibiotic from the enzyme, or the time required to synthesize new DNA gyrase.[80]

In addition to the specific drug-microbe combination, the magnitude and duration of drug exposure also have an impact on the PAE. Cell wall–acting agents (e.g., β-lactams and glycopeptides) demonstrate a concentration-dependent PAE. Increases in the concentration and duration of exposure (i.e., increasing AUC) prolong the PAE

in both gram-positive and gram-negative organisms to a point of maximal effect, typically 2 to 6 hours, although the time may be shorter for some members of this class. In fact, the PAE appears to be related to the log-normalized AUC in a sigmoidal manner.[35,90,125] Similarly, an increasing concentration of protein synthesis inhibitors is associated with progressive prolongation in PAE to a point of maximal effect. However, it can be difficult to establish with the aminoglycosides and fluoroquinolones because complete killing at supratherapeutic concentrations can obscure accurate determination of the PAE.[36,106] Bacteriostatic agents generally demonstrate concentration-independent PAEs such that increasing the duration of antibiotic exposure, but not the concentration, results in an increase in PAE to some maximal effect.[36]

As expected, the magnitude of the PAE also depends on whether antimicrobial agents are administered alone or in combination. Indifferent, additive, and synergistic PAEs all have been described with the use of combination therapy.[68,87,106] However, for some drug-microbe combinations, the magnitude of the PAE may differ with the phenotypic expression of resistance. For *Enterococcus faecalis* isolates that demonstrate only low-level resistance to streptomycin or gentamicin, the effect of a penicillin-aminoglycoside combination on the PAE is markedly synergistic. In contrast, for isolates with high-level resistance to the aminoglycosides, no synergistic PAE is observed.[236] Additionally, physicochemical factors can affect in vitro determination of PAEs and, although the in vivo relevance is questionable, some are worthy of consideration. In *S. aureus*, the PAEs of penicillin and gentamicin are markedly protracted at the slightly acidic pH 6 as compared with a physiologic pH of 7.4. Given that a relatively acidic pH can occur at the site of active infection, a disease-PAE interaction is possible. A similar pH-dependent effect on PAE is not observed with the fluoroquinolones or macrolides against *S. aureus*, nor is it noted for *E. coli* and *P. aeruginosa* with the β-lactams, fluoroquinolones, and macrolides.[69,86] An increase in PAE in vitro also is observed as temperature drops, a finding that raises the question whether the PAE is truly altered or the generation time is lengthened. Regardless, the temperatures evaluated were much lower than physiologic temperatures and probably have no clinical impact in the presence of infection. Finally, anaerobic conditions are observed to increase the PAE for ciprofloxacin/*E. coli* and gentamicin/*S. aureus* combinations, but not with other combinations.[69]

The attention paid to PAE of late highlights its significance, which lies in the flexibility that it affords to extend the dosing interval before reexposure to drug, essentially redosing, is necessary. Researchers suggested that agents with a small PAE require that a dosing interval be selected that will maintain concentrations above the MIC throughout most of the interval. Agents with a more protracted PAE can be given less often and thus at higher doses, thereby supporting the argument for once-daily dosing with drugs such as the aminoglycosides. However, many nuances can be identified between the in vitro conditions under which PAEs are determined and the in vivo conditions of infection such that the ultimate clinical (i.e., therapeutic) implications of these data have yet to be determined. In vitro, attempts are made to remove the drug completely (i.e., abruptly terminate drug exposure to the microbe) after initial exposure when determining the PAE. In contrast, drug concentrations fall in a more controlled, typically first-order fashion in vivo. The impact of this distinction on PAEs in patients remains unknown. Variable growth rates or metabolic states of the organism when growing in vivo similarly may have an impact on the PAE. In vitro, a prolonged PAE is observed when *Enterococcus faecium* is exposed to the combination of gentamicin and penicillin; yet, when the same drug concentrations and the same inoculum size are achieved in the vegetation of a murine aortic valve endocarditis model, no prolongation of PAE can be observed.[95] Similarly, a rat model of *P. aeruginosa* endocarditis failed to demonstrate a PAE in vivo for the combination of imipenem and gentamicin despite a PAE of nearly 5 hours determined in vitro; however, an observable PAE in vitro and in vivo was noted in the same model when ciprofloxacin was evaluated.[94,105]

Impact of Inoculum Size on the Concentration-Effect Relationship

The antimicrobial effect observed at any given drug concentration may vary with the number of organisms at the site of infection. Accordingly, the size of the inoculum can be a primary determinant of drug efficacy. Early investigations clearly demonstrated that the duration of the infection before treatment is a significant predictor of clinical response.[47] When therapy is delayed, presumably leading to a larger inoculum, the efficacy of that therapy often is affected adversely. In non-neutropenic rats, larger doses of antibiotic were needed to treat *K. pneumoniae*, whether administered by continuous or intermittent infusion, when the infection was allowed to progress 34 hours before therapy was initiated versus 5 hours.[188] Many potential mechanisms have been proposed to account for this event. Large inocula perhaps generate a higher local density of enzymes that effectively reduce active (i.e., functional) antibiotic concentrations at the site of infection. Large bacterial populations also are statistically more likely to contain resistant organisms that arise by spontaneous mutation and predominate within the population as a result of the selective pressure posed by the antibiotic. One such example has been observed in a murine model of group A streptococcal myositis, in which the activity of penicillin is compromised most severely in the presence of a large inoculum (10^8 to 10^9 CFUs/mL), with relatively little impact on the activity of clindamycin. Given that the isolate did not produce β-lactamase and any residual PAE was irrelevant because both regimens maintained drug concentrations above the MIC for the duration of the dosing interval, this effect of the inoculum was attributed in part to the selection of a cell wall–deficient mutant.[210] Clindamycin, however, is not devoid of susceptibility to the inoculum effect for all organisms; an increase in the size of the inoculum or an increase in the time until therapy resulted in a lower reduction in $\log_{10}$CFUs in a murine *Bacillus*

fragilis abscess model.[111] Another proposed mechanism for the effect of the inoculum lies in the finding that dense populations of organisms may grow at a slower rate or be metabolically inactive when compared with their less dense counterparts. An effect arising by this mechanism probably will not affect antimicrobial agents that are bactericidal against both rapidly growing and stationary-phase organisms (e.g., fluoroquinolones). However, for agents that exert their bactericidal effects primarily on rapidly dividing organisms (e.g., β-lactams), activity may be compromised in the presence of an established infection in which the bacterial population is large and as many as 90 percent of the organisms may be slowly dividing and, thus, metabolically inactive. For clinical isolates of group G streptococci, time-kill studies demonstrated rapid complete bacterial killing when the organism was primarily in log-phase growth, regardless of whether 10^4 or 10^7 organisms were involved. In contrast, when the organism was principally in the stationary phase, rapid and complete killing was observed only for the smaller inoculum (10^4 organisms), with no appreciable killing at 10^8 organisms. Furthermore, in patients with a protracted clinical course of infection or recalcitrant infection, therapy failed despite high drug doses and the presence of a susceptible isolate.[129]

Attempting to link multiple pharmacodynamic effects in evaluating the outcome of anti-infective therapy poses an arduous task from both theoretical and practical perspectives, and, hence, a complete discussion is not undertaken in this chapter. Nonetheless, the combination of such effects has received some attention in the literature and merits mention. Specifically, large inocula appear to be capable of modulating the PAE and subinhibitory effects observed with numerous agents. Exposure of *E. coli* to subinhibitory sparfloxacin concentrations produced a pronounced inoculum-dependent subinhibitory effect. At a dose that was 0.3 times the MIC, growth of the organism was delayed by 0.3, 0.9, and 3.3 hours with inocula of 10^8, 10^6, and 10^4 CFUs, respectively, with similar observations noted for other drug-microbe combinations.[35,162]

Concentration-Dependent Combination Effects (Synergy and Antagonism)

As discussed earlier and elsewhere in this text, antimicrobial combinations are used for many purposes: to prevent or delay the emergence of resistance, to enable dosage reduction and thereby minimize dose-related toxicities, and to treat polymicrobial infections. Combination therapy can be designed with the goal of synergistic or additive activity in mind, or, alternatively, these effects can occur without conscious consideration or forethought. Moreover, the undesirable outcomes of indifference or antagonism similarly can result through the combination of agents. Although a complete review of antagonism and synergy is beyond the scope of this section, we would be remiss not to mention concentration-dependent combination effects. We provide this brief discussion specifically to point out that a simple classification of drug combinations as synergistic, antagonist, and so forth is not always feasible. As discussed elsewhere, disagreement in the classification certainly can arise when different methods are used for evaluation.[21,160]

However, even when restricted to evaluations using the same experimental methods, certain combinations can be classified differently, depending on antibiotic concentration. Synergy is observed with cefoperazone and low imipenem concentrations against MRSA; however, higher concentrations of imipenem antagonize the activity of cefoperazone. Although antagonism with imipenem often is explained away as being β-lactamase mediated, the concentration-dependent antagonism observed remains unexplained by this mechanism because antagonism was shown for strains that lacked β-lactamase production.[178] The combination of penicillin and clindamycin at subinhibitory concentrations demonstrates synergy against group A β-hemolytic streptococci. At concentrations ranging from two to four times the MIC, the combination demonstrates antagonism, and at clinically relevant concentrations (≈100 times the MIC), indifference is observed, with the combination exhibiting no advantage over either agent alone.[211] Against isolates of vancomycin-intermediate *S. aureus*, antagonism is observed when methicillin and vancomycin are combined at subinhibitory concentrations. However, when the methicillin concentration exceeds the MIC, synergy is observed with the same combination. Although the mechanism behind this differential activity remains unclear, researchers proposed that the antagonism observed at lower methicillin concentrations results from an increase in the density of non–cross-linked D-alanyl-D-alanine side chains, the target site for vancomycin and a substrate for the PBPs. This increase would decrease the efficacy of methicillin as a PBP inhibitor by substrate competition.[99] For certain strains of methicillin-sensitive *S. aureus*, a combination of rifampin and methicillin below the MIC is synergistic, but above the MBC it is antagonistic. Similarly, a rifampin-vancomycin combination is synergistic at concentrations close to the MBC but indifferent as concentrations rise.[242] Furthermore, for some drug-microbe combinations, it is not the classification per se that is affected by the concentration but rather the magnitude of the effect observed. Against *E. faecium*, fixed piperacillin and variable teicoplanin concentrations are synergistic. However, the degree of synergy depends on the teicoplanin concentration; comparable synergistic activity occurs at teicoplanin concentrations of 2, 4, or 8 mg/L; reduced synergistic activity occurs at teicoplanin concentrations of 16 and 32 mg/L; and the greatest degree of synergy is observed at a concentration of 64 mg/L.[180]

Thus, the available data support the finding that, in many cases, the clinical assignment or "expectation" of synergy, additivity, or antagonism by specific combinations of anti-infective agents cannot be assumed simply by virtue of the drug class or drug-specific mechanisms of action, or both. With drug combinations for which the activity against an infecting pathogen is potentially concentration dependent, prediction of therapeutic outcome must entail some assessment, be it actual or theoretical (e.g., the use of pharmacokinetic modeling), of the time-dependent drug concentration profile at the site or sites of infection.

PHARMACOGENETIC DETERMINANTS OF EFFECT

Although this chapter is designed to detail the pharmacokinetic and pharmacodynamic determinants of anti-infective drug response, we would be remiss not to introduce the emerging role of pharmacogenetics as a predictor of drug response and a driver of anti-infective drug therapy. Although the application of molecular biology to infectious diseases traditionally has been limited to diagnostics (e.g., polymerase chain reaction–based assays for the detection of viral pathogens and slow-growing microorganisms) and disease monitoring (e.g., viral loads), molecular tools increasingly are finding application with identifying the likelihood of drug response a priori and determining optimal treatment strategies for infectious pathogens. Genotyping strategies are used to identify mutations that confer drug resistance and guide the selection of antiretroviral therapy in management of human immunodeficiency virus infection.[134,227] Similarly, viral genotyping appears to be among the most robust predictors of response to combination therapy in the treatment of hepatitis C virus,[130,191] and it has prompted similar investigations for hepatitis B virus.[88,118] Finally, commercially available molecular-based assays have been developed for the determination of methicillin resistance in *S. aureus*, multidrug resistance in *M. tuberculosis*, and vancomycin resistance in *Enterococcus* in clinical isolates. These kits appear to perform well when compared with conventional phenotype-based methods.[121,152,166] However, the degree of integration for these kits into routine clinical practice remains to be determined.

FURTHER CONSIDERATIONS

As denoted earlier in the chapter, there are numerous studies that have explored pharmacodynamic surrogates for agents active against invasive fungal pathogens. Given the marked mortality rates associated with invasive fungal disease and the increasing number of pediatric patients requiring antifungal therapy, a few caveats surrounding susceptibility testing should be addressed.[150,173] The Clinical and Laboratory Standards Institute (CLSI) has published guidelines for susceptibility testing of *Candida* spp.; however, standardizing and interpreting MIC results for filamentous fungi (molds) remains complex.[33] Standardizing inoculum concentrations across the wide variety of molds can be challenging, determining the MIC end point is difficult as a reduction of turbidity is not easily visualized with molds, and discriminating drug effects from drug-solvent combination effects can be misleading.[65] Thus, the correlation between drug exposure and treatment success in children remains unclear and is largely based on clinical observation of the patient. Further investigation in the pharmacokinetic-pharmacodynamic interface for antifungal agents is critical with the continued need to identify surrogate measures to allow for optimizing therapy.

CONCLUSIONS

With a recognized decline in the development of new antimicrobial therapies over the past 2 decades and the emergence of multidrug-resistant organisms (e.g. gram-negative organisms, *Mycobacterium tuberculosis*), a continued need persists for the re-purposing of older agents while awaiting the future development of newer therapies.[208] Unfortunately, there remains a relative paucity of pharmacokinetic-pharmacodynamic information for many of the currently available antimicrobial agents in children (e.g., antitubercular agents); and for older agents that continue to hold important places in pediatric therapeutics (e.g., metronidazole, clindamycin), complete profiles of their clinical pharmacology (i.e., absorption, biotransformation) in infants and children are lacking.[81] For both existing and emerging drug therapies, pharmacokinetics provides a powerful and valuable tool. The clinical scientist can use pharmacokinetics to characterize a given drug by providing a profile of its absorption, distribution, metabolism, and excretion in individuals with and without disease, during normal alterations of human physiology (e.g., pregnancy), as well as under conditions of normal altered organ function or body composition (e.g., growth and development, senescence). For the clinical practitioner, the tool of pharmacokinetics can provide a means to individualize drug therapy by characterizing the relationship between drug dose and resultant drug concentrations in plasma or other relevant biologic fluids (e.g., urine, CSF, synovial fluid, pleural fluid, peritoneal fluid). When linked with information regarding the pharmacodynamic behavior of the antibiotic, the susceptibility of the organism, and the status of the host, the application of pharmacokinetics affords the practitioner the ability to exercise some degree of adaptive control over drug therapy by selecting a drug and dosing regimen that have the greatest likelihood of producing both efficacy and safety.

CHAPTER 235

Antibacterial Therapeutic Agents

Carla Garcia • George H. McCracken, Jr.

This review of the use of antimicrobial agents is divided into two sections: (1) the clinical pharmacology of currently available antibacterial drugs and (2) the various aspects of administration of antimicrobial agents to infants and children. The second section includes dosage schedules and routes, prophylactic use of antimicrobial agents, considerations in writing orders and prescriptions, and other aspects of administration. Drugs of value in the treatment of disease caused by viruses, fungi, mycobacteria, and parasites are discussed in other chapters dealing with these pathogens. For the most part, only antimicrobial agents approved for use in infants and children by the U.S. Food and Drug Administration (FDA) are discussed, although promising new agents that are likely to be approved are mentioned where relevant.

CLINICAL PHARMACOLOGY

The antibacterial agents of value in treating infectious diseases in infants and children may be classified into three major groups:

1. Agents that target cell wall or cell membrane: these agents include the following:
   - The β-lactams, including penicillins, cephalosporins, carbacephems, monobactams, and carbapenems
   - The glycopeptides (i.e., vancomycin)
   - The lipopeptides (i.e., daptomycin)
   - The polymyxin: colistin
2. Agents that interfere with protein synthesis, including the following:
   - Agents that bind the 30S subunit, including aminoglycosides, chloramphenicol, and tetracyclines
   - Agents that bind the 50S subunit, including macrolides, clindamycin, and linezolid
   - Other mechanisms: Rifamycins
3. Agents that target nucleic acids, including fluoroquinolones, sulfonamides, and metronidazole

The following properties that govern the use of each group of drugs in infants and children are considered: mechanism of action, mechanisms of resistance, in vitro efficacy, pharmacokinetics, therapeutic uses, available preparations, and side effects and toxicity.

AGENTS THAT TARGET THE CELL WALL

β-Lactams

Biochemical Structure

The β-lactams are a large group of compounds that have in common a four-membered β-lactam ring. The subclasses of β-lactams differ from one another with regard to their side chains and the presence of other ring structures: the penicillins contain a five-membered thiazolidine β-ring fused to the β-lactam ring,[173] the cephalosporins have a six-membered dihydrothiazine instead of the thiazolidine ring, and the carbacephems have a methylene group replacing the sulfur atom in the dihydrothiazine ring of the cephalosporin nucleus. The β-lactam ring is essential for antibacterial activity, whereas the side chains influence the pharmacologic properties of the β-lactam and the spectrum of antibacterial activity.

Mechanism of Action

Our understanding of the mechanism of action of the β-lactams has evolved over the past 3 decades. Previously, researchers thought that binding of β-lactam to a bacterial cell membrane–associated enzyme (transpeptidase) blocked the terminal step in synthesis of the peptidoglycan layer of the bacterial cell wall. Cell death would ensue because the weakened cell wall could not withstand the osmotic and mechanical pressure resulting from a growing bacterium.[303] More recent evidence suggested that it is a more complex process involving activation of endogenous autolytic systems[218,305] and inhibition of bacterial enzymes called the *penicillin binding proteins* (PBPs), which include transpeptidase, carboxypeptidase, and endopeptidase. These enzymes are located beneath the cell wall and are responsible for cell wall synthesis by achieving cross-linkage between peptide chains of peptidoglycans. PBPs are vital for cell division, cell shape, and structural integrity. Because the specific PBPs within each bacterial species and the affinity of each β-lactam antibiotic for a particular PBP differ, some β-lactams have better activity than others against particular bacteria. The various β-lactam antibiotics can have different morphologic effects on the same bacterial species; this property is thought to be related to specific functions of the PBP to which the β-lactam binds.[287] Some bacteria

have a deficiency in the system of autolytic enzymes that results in inhibition, but not killing of the bacteria by a β-lactam that otherwise would be bactericidal. This phenomenon is termed *tolerance* and is demonstrated in vitro by a minimal inhibitory concentration (MIC) in the susceptible range and a ratio of minimal bactericidal concentration (MBC) to MIC of 32 or greater.[133]

Lactam antibiotics are bactericidal against most susceptible bacteria. The nature of the bactericidal activity has been described as time-dependent, as opposed to the concentration-dependent bactericidal activity of aminoglycosides.[188] Bactericidal activity is thought to be optimal when the concentration of β-lactam antibiotic at the site of infection is 4 to 10 times greater than that of the MIC (or MBC) of the infecting organism. The rapidity and extent of killing are not increased when concentrations exceed that ratio. A more important determinant of bactericidal activity for β-lactams is the length of time during the dosing interval that the concentration of antibiotic exceeds the MIC (time > MIC) for the infecting organism. Optimal bacterial killing correlates with time greater than MIC that exceeds 40 to 50 percent of the dosing interval.[80]

Penicillins

Although first discovered by Fleming in the late 1920s, penicillin G was not available for general use in the United States for another 20 years. Since that time, numerous semisynthetic penicillins have been developed. The penicillins can be classified into four groups based on their antimicrobial activity, with some overlap (Table 235-1). The spectrum of activity among the compounds within each group usually is similar; the differences are attributable to their pharmacologic properties (Table 235-2).

Penicillin G and Penicillin V

Despite the more than 50 years that penicillin G has been in use, some bacteria continue to be exquisitely susceptible. Resistant strains of *Streptococcus pyogenes* (group A streptococcus) and *Streptococcus agalactiae* (group B streptococcus) have not emerged. Penicillin G remains the drug of choice for the treatment of disease caused by a wide variety of microorganisms (Table 235-3).

The mechanism by which most bacteria have acquired resistance to penicillin G is that of β-lactamase production; resistance caused by altered PBPs occurs less commonly. Most strains of *Staphylococcus aureus* and *Staphylococcus epidermidis* produce penicillinase. *Neisseria gonorrhoeae* gradually developed resistance to penicillin G beginning in the late 1960s by various mechanisms, including plasmid-mediated production of a TEM1-like β-lactamase, as well as chromosomal mutations in at least four genes (*penA*, *penB*, *ponA*, and *mtrR*) that encode increased expression of an efflux pump and alterations in PBPs and porins.[238] Mechanisms of β-lactam resistance in *Bacteroides* spp. and other gram-negative anaerobes include production of class A lactamases (penicillinase or cephalosporinase) and class B metallo-β-lactamases that hydrolyze carbapenems, as well as alteration of PBPs.[17]

TABLE 235-1 **Classification Scheme for Penicillins**

Generic Name	Trade Name	Route
Natural Penicillins		
Penicillin G	Many	PO,* IM, IV
Penicillin V	Many	PO
Aminopenicillins		
Ampicillin	Many	PO, IM, IV
Amoxicillin	Many	PO
Amoxicillin/clavulanate	Augmentin	PO
Ampicillin/sulbactam	Unasyn	IM, IV
Bacampicillin	Spectrobid	PO
Penicillinase-Resistant Penicillins		
Cloxacillin	Cloxapen	PO
Dicloxacillin	Dycill, Dynapen, Pathocil	PO
Methicillin	Staphcillin	IM, IV
Nafcillin	Nafcil, Nallpen, Unipen	IM, IV, PO
Oxacillin	Bactocill, Prostaphlin	IM, IV, PO
Extended-Spectrum Penicillins		
Ticarcillin	Ticar	IM, IV
Ticarcillin/clavulate‡	Timentin	IV
Mezlocillin	Mezlin	IM, IV
Piperacillin†	Pipracil	IM, IV
Piperacillin/tazobactam†	Zosyn	IV

†Safety and efficacy have not been established for children younger than 2 months.
‡Safety and efficacy have not been established for children younger than 1 month.
IM, Intramuscularly; *IV,* intravenously; *PO,* orally.

Historically, penicillin has been the antibiotic of choice for treatment of *Neisseria meningitidis* infections, but strains with reduced susceptibility to penicillin have been reported in Europe, South America, Asia, Australia, and the United States, where approximately 15 percent of strains have alterations in PBP2 encoded by the *penA* gene that likely results from mosaic genes derived through transformation with DNA from commensal *Neisseria* spp. in the nasopharynx of colonized individuals. Although penicillin resistance resulting from production of β-lactamase has been reported, such strains are rare.[161]

Of particular concern is the global dissemination of strains of *Streptococcus pneumoniae* resistant to penicillin G as a result of altered PBPs. The first documented clinical case of infection caused by penicillin-resistant pneumococcus was reported in 1967 from Australia. Surveillance data in the United States estimated the average rate of penicillin nonsusceptibility to be 33 percent (high-level resistance, 16%), with the highest incidence of 44 percent reported in the south-central region.[156] However, since the introduction of the 7-valent

TABLE 235-2 **Pharmacokinetics of Penicillins**

Antibiotic	Oral Absorption (%)	Protein Binding (%)	Metabolized (%)	Urinary Recovery* (%)	Approximate Half-Life† (hr)

†Only those without altered penicillin binding proteins.

pneumococcal conjugate vaccine (PCV7) in 2000, invasive pneumococcal disease in young children caused by vaccine serotypes decreased by approximately 90 percent. Conversely, invasive disease caused by nonvaccine serotypes increased.[181] The incidence of disease caused by 19A serotype increased, and these isolates are associated with β-lactam antibiotic resistance (including penicillin and third-generation cephalosporins).[143,295] The Active Bacterial Core Surveillance (ABC) report from 2010 showed penicillin nonsusceptibility of 10.6 percent and cefotaxime nonsusceptibility of 8.6 percent.[65] Currently, approximately 6 percent of pneumococci in the United States exhibit a multidrug-resistance phenotype defined as resistance to penicillin, trimethoprim-sulfamethoxazole (TMP-SMX), erythromycin, clindamycin, and tetracycline.[156] Although penicillin-resistant pneumococcal meningitis has developed in patients who were receiving vancomycin for pneumococcal sepsis,[69] no treatment failures have been documented when the appropriate dosage of vancomycin was administered. In 2010, a 13-valent pneumococcal vaccine (PCV13) that includes serotype 19A was implemented. Epidemiologic surveillance continues to establish changes in trends for invasive pneumococcal disease.

In 2008, the Clinical and Laboratory Standards Institute (CLSI; formerly the National Committee for Clinical Laboratory Standards) published new *S. pneumoniae* breakpoints for penicillin because of a reevaluation that showed clinical response to penicillin was being preserved in clinical studies of pneumococcal infection, despite reduced susceptibility in vitro. Under the former criteria, susceptible, intermediate, and resistant MIC breakpoints for penicillin were less than 0.06, 0.121, and greater than 2 μg/mL, respectively, for all pneumococcal isolates, regardless of clinical syndrome or route of penicillin administration. Those breakpoints remain unchanged for patients without meningitis who can be treated with oral penicillin. However, for patients without meningitis who are treated with intravenous penicillin, the new breakpoints are less than 2, 4, and greater than 8 μg/mL, respectively. Furthermore, isolates from patients with meningitis are now categorized as either susceptible or resistant, with intravenous penicillin breakpoints of less than 0.06 or greater than 0.12 μg/mL, respectively. Use of narrow-spectrum agents, such as penicillin, is encouraged to prevent the spread of antimicrobial-resistant *S. pneumoniae* and also the spread of methicillin-resistant *S. aureus* and *Clostridium difficile*,

which can result from use of broader spectrum antimicrobials.

Several oral and parenteral forms of penicillin G are available. Selection of a preparation is based on the pattern of antimicrobial activity, including the peak and duration of activity in serum and tissues, and factors that reflect absorption, distribution, and excretion of the drug. These characteristics of penicillins are as follows:

1. Aqueous (water-soluble) penicillin G produces high peak concentrations of antibacterial activity in serum within 30 minutes after intramuscular administration but is excreted rapidly; thus, the concentration in serum is low within 2 to 4 hours. If aqueous penicillin G is given by the intravenous route, the peak is higher and occurs earlier, and the duration of antibacterial activity in serum is shorter (≈2 hours). Aqueous penicillin G given intravenously is used for severe disease such as meningitis, complicated pneumonia, and endocarditis caused by susceptible pathogens. In such cases, the drug should be administered at frequent intervals, usually every 4 hours, until the infection has been controlled.
2. Procaine penicillin G given intramuscularly produces lower concentrations of serum antibacterial activity (≈10% to 30% of the peak concentration achieved by the same dosage of the aqueous form), but activity persists in serum for as long as 12 hours. Intramuscular administration of procaine penicillin G should be reserved for patients with mild-to-moderate disease who cannot tolerate oral preparations. A 10-day course of this agent may be used as an alternative to intravenously administered aqueous penicillin G for infants with documented or suspected congenital syphilis.[316]
3. Benzathine penicillin G given intramuscularly is a repository preparation that provides low concentrations of serum activity (≈1% to 2% of the peak concentration achieved by the same dosage of the aqueous form). After administration of this drug, concentrations of penicillin are measurable in serum for 3 weeks or more and in urine for several months. Pain at the site of injection is the major deterrent to widespread use of this unique antibiotic. A combination of the benzathine and procaine salts (900,000 and 300,000 U, respectively) is a less painful treatment and is comparable in efficacy to benzathine alone (1,200,000 U) for the treatment of streptococcal pharyngitis.[25] Benzathine penicillin G is appropriate for only highly sensitive organisms present in tissues that are well vascularized so that the drug can diffuse readily to the site of infection. Thus, benzathine penicillin G is suitable for treatment of children with group A streptococcal pharyngitis or impetigo and for prophylaxis of streptococcal infection in children who have had rheumatic carditis. Current recommendations by the Centers for Disease Control and Prevention (CDC)[316] for management of syphilis include the use of benzathine penicillin G for primary, secondary, and early latent syphilis (<1 year's duration). Benzathine penicillin G also is recommended for infants with suspected congenital syphilis who do not meet the criteria for therapy with a 10-day course of aqueous or procaine penicillin G and whose follow-up can be ensured for repeat serologic testing.
4. Oral preparations of buffered penicillin G (no longer available in the United States) and phenoxymethylpenicillin (penicillin V) are absorbed well from the gastrointestinal tract. The peak concentration of serum activity of penicillin V is approximately 40 percent, and that of buffered penicillin G is approximately 20 percent of the concentration achieved by the same dosage of aqueous penicillin G administered intramuscularly. Therefore, oral penicillins may be satisfactory for treating mild to moderately severe infections caused by susceptible organisms. Penicillin V and penicillin G have equivalent activity in vitro against gram-positive cocci, but penicillin V is less active than is penicillin G *against N. meningitidis*, *N. gonorrhoeae*, and susceptible strains of *Haemophilus influenzae*.[173] The benefit of treating streptococcal tonsillopharyngitis with a 10-day regimen of penicillin V for the prevention of acute rheumatic fever is based on indirect evidence derived from rates of pharyngeal eradication of *S. pyogenes* equivalent to those of injectable penicillin, the treatment with proven efficacy.[90,281]

All penicillins are excreted by both glomerular filtration and tubular secretion. The concomitant use of probenecid, a drug that blocks tubular secretion of organic acids, with a penicillin can produce higher peaks and more sustained concentrations of antimicrobial activity. Dosages and dosing intervals may need adjustment when penicillins are administered to persons with altered renal function.

Penicillinase-Resistant Penicillins

The semisynthetic penicillinase-resistant penicillins were developed in response to the emergence of penicillinase-producing staphylococci. The acyl side chain, by means of steric hindrance, prevents hydrolysis of the β-lactam ring by penicillinases. Most strains of *S. aureus* produce penicillinase, regardless of whether the infection is health care–associated or community acquired. In areas of low rates of resistance to β-lactams, penicillinase-resistant penicillins are the β-lactams of choice for the initial management of patients with suspected staphylococcal disease. However, alternative effective antimicrobials should be substituted or added if endemic rates of antibiotic resistance exceed 10 to 15 percent or if the severity of the disease warrants empirical treatment of methicillin-resistant *S. aureus* (MRSA).[123] With the exception of methicillin, these agents are active against streptococci and can be used for empirical treatment of infections commonly caused by both staphylococci and streptococci. Because these agents are less active than penicillin G against streptococci, penicillin G should be used instead of these agents if streptococci alone are isolated from culture. Penicillinase-resistant penicillins have no activity against gram-negative bacteria or enterococci.[203]

Methicillin was the first penicillinase-resistant penicillin to be introduced and was available in parenteral form only. Oxacillin and nafcillin are available in both parenteral and oral preparations. Cloxacillin and dicloxacillin are available in oral forms only and are absorbed more efficiently from the gastrointestinal tract than the other oral drugs. Differences among these five penicillins include routes of elimination, degree of binding to proteins and degradation by β-lactamases, and in vitro susceptibility.[229] However, all are effective in the treatment of susceptible strains of staphylococcal isolates, and clinical studies have shown them to be equivalent when used at appropriate dosage schedules. Suspension formulations are poorly tolerated because of their unpleasant taste. Disease caused by methicillin-resistant staphylococci was reported shortly after introduction of the drug in the 1960s. Resistance is caused by alterations in PBPs, rather than production of β-lactamase. The *mecA* gene encodes a new PBP2a that has low affinity for β-lactams, thereby resulting in resistance to most β-lactam antibiotics currently available, including penicillinase-resistant penicillins, cephalosporins (first to fourth generation), and carbapenems. The *mecA* gene is carried on one of four mobile genetic elements known as the staphylococcal chromosomal cassette (SCC)mec I to IV that differ in size and the presence of additional resistance genes. The mechanisms of resistance to other antibiotics are unrelated to PBPs and may be plasmid mediated or chromosomal.[200] SSCmec IV is traditionally found in community-acquired strains of MRSA (CAMRSA) that are not associated with multidrug resistance, whereas SSCmec I to III are found typically in health care–associated strains that are resistant to multiple antibiotics, including aminoglycosides, clindamycin, fluoroquinolones, fusidic acid, macrolides, rifampin, sulfonamides (TMP-SMX), and tetracyclines.[259] However, these distinguishing characteristics are tending to merge as *S. aureus* becomes increasingly resistant. Coagulase-negative staphylococci, including *S. epidermidis*, are residents of the normal microbial flora of the skin and are occasional contaminants of body fluid cultures. These organisms can be pathogens in certain settings, such as in neonates, or in infections of prosthetic devices, such as heart valves or cerebrospinal fluid (CSF) shunts. Most strains of coagulase-negative staphylococci produce a penicillinase that inactivates penicillin G, penicillin V, and ampicillin, and many strains have *mecA*-mediated altered PBP2a, leading to methicillin resistance. In addition, these methicillin-resistant, coagulase-negative staphylococci frequently are resistant to cephalosporins, erythromycin, and clindamycin. Vancomycin is the drug of choice for pathogenic coagulase-negative staphylococci and severe disease known or suspected to be caused by MRSA. Some experts advocate the addition of nafcillin or oxacillin for empirical therapy for suspected MRSA in patients who are severely ill, although toxicity may be increased with combination therapy.[109,123]

Aminopenicillins

The aminopenicillins are semisynthetic β-lactam antibiotics formed by the addition of an amino group to benzylpenicillin. Amoxicillin differs from ampicillin by the presence of a hydroxyl group on the phenyl side chain. The aminopenicillins were the first penicillins that had activity against some gram-negative organisms, including *H. influenzae*, *Escherichia coli*, *Proteus mirabilis*, *Salmonella* spp., and *Shigella* spp., while retaining activity against penicillin-susceptible, gram-positive bacteria.[228]

In contrast to penicillin G, aminopenicillins are significantly more active against *Listeria monocytogenes*, slightly more active against enterococci, equally active against *Actinomyces*, *N. meningitidis*, and clostridial and corynebacteria species, and slightly less active against group A streptococci, group B streptococci, and pneumococci. Aminopenicillins are the drugs of choice for the treatment of infections caused by *L. monocytogenes* and enterococci. Other organisms susceptible in vitro to ampicillin and amoxicillin include non–penicillinase-producing strains of *H. influenzae*, *Moraxella catarrhalis*, *N. gonorrhoeae*, *S. aureus*, *E. coli*, *Salmonella*, and *Shigella*. A survey of health care–associated and community-acquired *H. influenzae* and *M. catarrhalis* strains isolated from the blood and respiratory tracts of children in North America documented ampicillin resistance rates of 34 percent and 99 percent, respectively.[160] The in vitro spectrum of activity for amoxicillin and ampicillin is identical, except amoxicillin is two times less active against *Shigella* and two to four times more active against enterococci and *Salmonella* than ampicillin.[228]

As seen with penicillin G, the primary means of acquired resistance to aminopenicillins is the production of β-lactamase. However, organisms that are resistant to penicillin G or to methicillin because of altered PBPs—*S. pneumoniae* and *S. aureus*, respectively—also are resistant to aminopenicillins. Lactamase-negative, ampicillin-resistant strains of *H. influenzae* have been identified in the United States much less frequently than in Japan (0.2% vs. 2.6%, respectively).[150]

The broad-spectrum bactericidal activity of ampicillin and amoxicillin provides the basis for the use of these drugs as empirical therapy for lower respiratory tract infections and acute otitis media, for which amoxicillin remains the drug of choice.[10] Ampicillin or penicillin G is the recommended initial empirical therapy in community-acquired pneumonia in a fully immunized infant or school-aged child admitted to a hospital ward if the local epidemiology reveals no substantial high-level resistance for invasive *S. pneumoniae*.[49] Aminopenicillins are indicated for treatment of susceptible strains of *Shigella*-associated or *Salmonella*-associated enteric infections as well as susceptible acute and chronic infections of the urinary tract. By bacteriologic and clinical measures, amoxicillin is significantly less effective than ampicillin for the treatment of shigellosis.[226]

Both drugs are available for oral administration; ampicillin alone is available in a parenteral form. Amoxicillin provides higher and more prolonged serum concentrations than those achieved with equivalent dosages of ampicillin; thus, amoxicillin can be given in lower dosage, two or three times per day, rather than four times, as required for ampicillin. An additional advantage of amoxicillin is that absorption is not altered when the antibiotic is administered with food, whereas absorption

of ampicillin is decreased significantly when it is given with food. Ampicillin is associated more frequently with diarrhea than is amoxicillin.

Extended-Spectrum Penicillins

Extended-spectrum penicillins are semisynthetic derivatives of ampicillin that have better activity against gram-negative organisms because of a higher affinity for PBPs and greater penetration through the gram-negative outer membrane. Carbenicillin and ticarcillin, the carboxypenicillins, have a carboxyl group replacing the amino group side chain of ampicillin, whereas the acylureidopenicillins have a ureido (urea) side chain (mezlocillin) or ureido and piperazine side chains (piperacillin). Their pharmacologic properties are similar and include susceptibility to hydrolysis by staphylococcal penicillinases and, to a lesser extent, the β-lactamases of gram-negative bacteria. They differ somewhat in their toxicities and spectrum of activity. An oral preparation, carbenicillin indanyl (Geocillin) is active against susceptible strains of *Pseudomonas aeruginosa*, but its production was discontinued in 2008.

The activity of carbenicillin is equivalent to or slightly less than that of ampicillin against non–β-lactamase-producing *N. gonorrhoeae*, *N. meningitidis*, *H. influenzae*, *E. coli*, *P. mirabilis*, *Salmonella* spp., and *Shigella* spp. It is less active than ampicillin against group A streptococci, pneumococci, and enterococci. Its activity is variable against many *Bacteroides fragilis*, *Enterobacter*, and *Serratia* organisms, and it is not active against *Klebsiella*.

The activity of ticarcillin is similar to that of carbenicillin, but it is two to four times more active against some strains of *P. aeruginosa* and less active against gram-positive cocci. In addition, ticarcillin can be used for infections caused by susceptible strains of *Acinetobacter*. Because of its increased activity, ticarcillin may be used in smaller doses than needed with carbenicillin for the treatment of disease caused by gram-negative organisms.

Piperacillin and mezlocillin are parenteral penicillins with a spectrum of activity similar to that of ticarcillin but greater activity in vitro against some gram-negative bacilli and anaerobic bacteria. In vitro studies against *P. aeruginosa* demonstrated that piperacillin has activity that is four times that of mezlocillin and ticarcillin and about eight times that of carbenicillin, the clinical significance of which is unknown. Piperacillin and mezlocillin are more active in vitro than carbenicillin or ticarcillin against susceptible strains of *E. coli*, *Klebsiella*, *Enterobacter*, *Serratia*, and *B. fragilis*. Furthermore, piperacillin, mezlocillin, and ticarcillin are effective in the treatment of infections caused by susceptible strains of *Citrobacter*, indole-positive *Proteus*, and *Providencia*. Carbenicillin and ticarcillin are disodium salts and contain 4.7 mEq (108 mg) and 5.2 mEq (120 mg) of sodium per gram, respectively. The acylureidopenicillins are monosodium salts that have a lower sodium content (1.9 to 2.2 mEq) than the carboxypenicillins. The amount of sodium administered may be of concern when treating certain patients with renal or cardiac disease. Hypokalemia with metabolic alkalosis occasionally occurs with the administration of extended-spectrum penicillins, especially the carboxypenicillins. The penicillin acts as a nonreabsorbable anion in the distal renal tubules, where it affects normal hydrogen exchange and secondarily results in loss of potassium. These extended-spectrum penicillins can bind to platelet adenosine diphosphate receptors and thereby result in abnormal platelet aggregation and prolonged bleeding times. This dose-related phenomenon occurs more frequently with the administration of ticarcillin than with the acylureidopenicillins. The effects on platelet function may be a consideration when choosing empirical therapy for a thrombocytopenic patient with suspected gram-negative infection.[318]

When carboxypenicillins or ureidopenicillins have been used as single agents for empirical treatment of patients with severe gram-negative infections, fever and neutropenia, or polymicrobial intra-abdominal infections, bacterial resistance has developed in 10 to 15 percent of cases during treatment. Combinations of extended-spectrum penicillins with an aminoglycoside demonstrate synergistic in vitro inhibition of certain gram-negative bacteria, including *P. aeruginosa*. Based on in vitro data and clinical experience, extended-spectrum penicillins should be combined with an aminoglycoside in some patients (particularly if immunocompromised) with severe infections, in case bacterial resistance develops.[318] All of the extended-spectrum penicillins are available in parenteral formulations only.

β-Lactam-β-Lactamase Inhibitor Combinations

β-Lactamase inhibitors are compounds that have weak antibacterial activity but can bind irreversibly to the catalytic site of many β-lactamases and render them inactive. The inhibitors currently in use are clavulanic acid, sulbactam, and tazobactam, the latter of which is halogenated penicillanic acid derivative. All three inhibitors are identical in their mode of activity but differ to some degree in their potency and spectrum of enzyme inhibition. These agents primarily inhibit the plasmid-encoded β-lactamases and less frequently the chromosomally encoded β-lactamases. β-Lactamase inhibitors have been formulated in a fixed ratio with a β-lactam antibiotic. The spectrum of activity of each combination is determined primarily by the spectrum of activity of the β-lactam. However, many determinants of the inhibitor influence its activity, including its affinity for the β-lactamase and its ability to traverse the gram-negative cell wall to bind to periplasmic β-lactamases.[192] From a clinical perspective, all three β-lactamase inhibitors are considered therapeutically equivalent. The β-lactamase inhibitors are most effective against *S. aureus*, *H. influenzae*, *M. catarrhalis*, *Bacteroides* spp., *E. coli*, and other Enterobacteriaceae. The main indication for the use of these combination antimicrobial agents is for the treatment of health care–associated infections or infections caused by susceptible β-lactamase–producing pathogens.

Amoxicillin–Clavulanic Acid. Amoxicillin combined with potassium clavulanate was introduced in 1984 for oral administration. The pharmacokinetic properties of

the two drugs are similar; both are absorbed rapidly and are not affected when taken with meals. Gastrointestinal side effects, including nausea, vomiting, and diarrhea, occur more commonly with amoxicillin-clavulanate than with amoxicillin alone.[172]

The combination drug is equivalent to amoxicillin alone in activity against amoxicillin-susceptible organisms. The addition of clavulanic acid extends the activity of amoxicillin to include β-lactamase–producing strains of *S. aureus* (but not methicillin-resistant strains), *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, *E. coli*, *Proteus*, *Klebsiella*, *Providencia*, *Haemophilus ducreyi*, and some anaerobic bacteria, including *B. fragilis*. Some β-lactamase–producing, gram-negative bacilli are resistant to amoxicillin–clavulanic acid because of either hyperproduction of β-lactamase or production of a β-lactamase that is not susceptible to clavulanate. Amoxicillin-clavulanate is not active against penicillin-resistant *S. pneumoniae* or vancomycin-resistant enterococci.

Amoxicillin is considered the preferred therapy for low-risk children with uncomplicated, mild to moderately severe disease of the respiratory tract, including initial empirical therapy for otitis media. In children who are at risk for penicillin-nonsusceptible pneumococcal acute otitis media, a 90-mg/kg daily regimen in two divided doses is recommended. Alternative therapy, including amoxicillin-clavulanic acid, should be considered if a β-lactamase–producing organism is known or suspected to be the cause of the disease based on risk factors, treatment experience, or microbiologic results. In 2001, high-dose amoxicillin–clavulanic acid suspension (Augmentin ES600; 600 mg of amoxicillin/5 mL and 42.9 mg of clavulanic acid/5 mL) was approved for use in children in the United States. The recommended dosage of this formulation is 90 mg/kg/day divided every 12 hours for the treatment of high-risk patients with acute otitis media.[10] The high ratio (14:1) of amoxicillin to clavulanate optimizes the amoxicillin dose without intensifying the risks for undesirable adverse effects associated with the β-lactamase inhibitor. The combination drug is useful in areas where the proportion of β-lactamase–producing strains of *H. influenzae* is large (30%) and *M. catarrhalis* organisms (most of which are β-lactamase producers) are identified more frequently as pathogens in otitis media, sinusitis, and other respiratory tract infections. Amoxicillin-clavulanate also has been used successfully for the oral treatment of urinary tract, skin, and soft tissue infections, as well as for the treatment of human and animal bite wounds.[58]

Ampicillin-Sulbactam. Ampicillin combined with sulbactam as a parenteral β-lactam and β-lactamase inhibitor combination was approved in 1987. The spectrum of activity of ampicillin-sulbactam is similar to that of amoxicillin-clavulanate. It is most useful as monotherapy for potential polymicrobial intra-abdominal or gynecologic infections and is effective for treatment of soft tissue, urinary tract, and respiratory tract infections. Ampicillin-sulbactam has been shown to be safe and efficacious for the treatment of skin and skin structure infections caused by susceptible organisms in children aged 3 months to 12 years.[19] The combination of ampicillin-sulbactam and an aminoglycoside has efficacy equivalent to that of a combination of ampicillin, clindamycin, and an aminoglycoside for empirical treatment of intra-abdominal infections in children.[74] Ampicillin-sulbactam is potentially useful for multidrug-resistant health care–associated infections caused by *Acinetobacter baumannii-calcoaceticus* complex.[221] Carbapenems and third-generation cephalosporins are comparatively more active against members of the Enterobacteriaceae. Because ampicillin-sulbactam has no activity against certain strains of the Enterobacteriaceae that produce Bush group 1 β-lactamases and *P. aeruginosa*, it should not be used as empirical single-agent therapy for febrile neutropenic patients or severely ill patients with probable bacteremia.

Ticarcillin–Potassium Clavulanate. Ticarcillin combined with potassium clavulanate was approved for use in 1985. It extends the spectrum of activity of ticarcillin to include β-lactamase–producing strains of staphylococci (but not methicillin-resistant strains), *H. influenzae*, *M. catarrhalis*, *E. coli*, *Klebsiella*, *Proteus*, *Providencia*, *N. gonorrhoeae*, and *B. fragilis*.[71] Ticarcillin-clavulanate also often is active against multidrug-resistant *Stenotrophomonas maltophilia*. Enterococci are moderately resistant to this agent. Because clavulanic acid does not inhibit Bush group 1–inducible chromosomal β-lactamases, *Citrobacter*, *Enterobacter*, and *Serratia* spp., as well as derepressed mutant strains of *P. aeruginosa* that are resistant to ticarcillin because of inducible cephalosporinases, also are resistant to ticarcillin–potassium clavulanate. Ticarcillin–potassium clavulanate is approved for use in children older than 3 months of age for lower respiratory tract, skin and skin structure, urinary tract, bone and joint, and intra-abdominal infections caused by susceptible pathogens.[38] Treatment of febrile neutropenic adult patients with ticarcillin-clavulanate combined with an aminoglycoside has been shown to be effective.

Piperacillin-Tazobactam. Piperacillin combined with tazobactam was approved for use in adults in 1993 and was approved for pediatric use (2 months to 17 years of age) in the United States in 2007.[306] It extends the spectrum of activity of piperacillin to include β-lactamase–producing strains of oxacillin-susceptible *S. aureus*, many members of the Enterobacteriaceae, and virtually all gram-positive and gram-negative anaerobes; its spectrum of activity is superior to that of ceftazidime and other β-lactam and β-lactamase inhibitor combinations. It has greater activity than ticarcillin-clavulanate against gram-positive and gram-negative bacteria and equivalent activity against gram-positive bacteria in contrast to ampicillin-sulbactam. Tazobactam, however, does not increase the activity of piperacillin against bacteria with resistance that is mediated by altered cell wall permeability to piperacillin, including certain strains of *P. aeruginosa*. Penicillin-resistant pneumococci, methicillin-resistant staphylococci, *Corynebacterium jeikeium*, most *Enterococcus faecium* strains, and most gram-negative bacteria that produce Bush group 1 β-lactamases (*Citrobacter*, *Enterobacter*, *Morganella*, certain strains of *Pseudomonas*, and *Serratia* spp.) are resistant to piperacillin-tazobactam.[58]

Although studies have shown piperacillin-tazobactam to be safe and effective for the treatment of lower respiratory tract, intra-abdominal, pelvic, skin and skin structure, bone, and diabetes-related foot infections in adults, as well as for empirical treatment of febrile episodes in neutropenic adults,[45] the experience in children is limited. It is a potentially useful agent that has been administered for the treatment of serious or complicated polymicrobial infections in children, especially in febrile neutropenic children, as initial empirical treatment. This antimicrobial agent should be used in combination with an aminoglycoside for serious *P. aeruginosa* infections to prevent the development of resistance. Piperacillin-tazobactam (or ticarcillin-clavulanate) has been proposed as an alternative treatment to carbapenems for single-agent therapy in community-acquired intra-abdominal infections.[286] Clinicians also should be aware that administration of piperacillin-tazobactam can cause false-positive *Aspergillus galactomannan* test results for up to 5 days after cessation of treatment.[16] Monte Carlo simulations have predicted achieving more time above the MIC_{50} with prolonged infusions of piperacillin-tazobactam (i.e., 4 hours) in contrast to conventional dosing, for MIC range MIC 4-16 mg/L. Similar results have been observed with other β-lactams, including meropenem, doripenem, cefepime, and ceftazidime. Clinical studies have not been conclusive.[201]

Adverse Effects and Sensitization

The penicillins are unique among antimicrobial agents in having little dose-related toxicity (Table 235-4). Seizures may occur under circumstances that result in high concentrations of penicillin in nervous tissue: rapid intravenous infusion of single large doses, substantial dosages for prolonged periods in patients with impaired renal function, or high concentrations given by the intrathecal route. Confusion, dizziness, seizures, and psychosis caused by toxic concentrations of procaine have been associated with the administration of procaine penicillin G.[284] Nephritis has been associated with the administration of some penicillins, most frequently after the use of methicillin. Bleeding because of drug-induced platelet aggregation has been noted after the administration of carbenicillin and penicillin G.

Although toxicity may not be a significant concern with the penicillins, sensitization is an important factor.[191] Penicillins are haptens, that is, they are low-molecular-weight compounds too small to elicit an immune response alone, but when bound to a carrier molecule (e.g., host tissues or proteins), they are highly immunogenic in humans. The native penicillin molecule can bind to a protein, as can its major (benzylpenicilloyl) and minor (benzylpenicillin, benzylpenicilloate, benzylpenilloate) determinants. Four types of immune-mediated reactions can occur after the administration of a penicillin (or any drug or antigen): immediate hypersensitivity (immunoglobulin E [IgE]-mediated) reactions, cytotoxic antibody reactions, immune complex reactions (Arthus reaction), and delayed (cell-mediated) hypersensitivity. Allergic reactions also can be classified as (1) immediate (onset ≤1 hour), accelerated (1 to 72 hours), or delayed (>72 hours).

TABLE 235-4 **Adverse Reactions to Penicillins**

Type of Reaction	Frequency (%)	Most Frequent*
Electrolyte Disturbance		
Sodium overload	Variable	Ticar
Hypokalemia	Variable	Ticar
Hyperkalemia, acute	Rare	PCN G
Gastrointestinal		
Diarrhea	2-5	Amp
Enterocolitis	<1	Amp
Hematologic		
Hemolytic anemia	Rare	PCN G
Neutropenia	1-4	PCN G, Naf, Ox, Pip
Platelet dysfunction	3	Ticar
Hepatic		
Elevated AST	1-4	Ox, Naf
Neurologic		
Seizures	Rare	PCN G
Bizarre sensations	Rare	Procaine PCN
Renal		
Interstitial nephritis	1-2	Meth
Hemorrhagic cystitis	Rare	Meth
Allergic		
IgE-mediated	0.004-0.4	PCN G
Cytotoxic antibody	Rare	PCN G
Immune complexes	Rare	PCN G
Delayed hypersensitivity	4-8	Amp

Modified from Chambers HF, Neu HC. Penicillins. In: Mandell GL, Bennett JE, Dollin R, editors. *Mandell, Douglas and Bennett's principles and practice of infectious diseases.* 4th ed. New York, Churchill Livingstone, 1995.
*All reactions can occur with any penicillin.
Amp, Ampicillin; *AST,* aspartate transaminase; *Meth,* methicillin; *Naf,* nafcillin; *Ox,* oxacillin; *PCN G,* penicillin G; *Pip,* piperacillin; *Ticar,* ticarcillin.

Researchers have estimated that an immediate serious reaction occurs in 2/10,000 courses, and fatal reactions occur in 1/100,000 treatment courses.[27,301]

1. Type 1 immediate hypersensitivity reactions usually occur within 30 minutes after administration and are life-threatening events. The interaction of preformed mast cell–bound IgE antibody to the antigenic determinants of penicillin results in the release of mast cell mediators.[41] Clinical signs include hypotension or shock, urticaria, laryngeal edema, and bronchospasm. Acute anaphylaxis is a rare event after the administration of penicillin, but significant numbers of fatalities occur each year because of the extensive use of these drugs. Children are thought to have fewer systemic reactions than do adults, presumably because of fewer previous exposures to penicillin antigens. Oral preparations are less likely to result in an immediate reaction than are parenteral forms, perhaps because

antigens are altered in the gastrointestinal tract, absorption is slower, dosages are smaller, or a combination of these factors.

2. Type 2 cytotoxic antibody reactions can occur after passive absorption of the benzylpenicilloyl hapten by the membrane of circulating blood cells or by renal interstitial cells, especially when high dosages of penicillins are used for prolonged periods. IgM antibody, IgG antibody, or both antibodies to the benzylpenicilloyl antigen bind to the altered cell surface; complement can be activated, and damage to the cell ensues. Cytotoxic antibody reactions usually are manifested more than 72 hours after initiation of antibiotic therapy and include hemolytic anemia, leukopenia, thrombocytopenia, and drug-induced interstitial nephritis.
3. Type 3 immune complex (Arthus) reactions occur after the formation of immune complexes between soluble penicillin antigens and IgG and IgM antibodies. The complexes lodge in the skin, joints, kidneys, or other tissue sites. Complement activation occurs, and the clinical manifestations of serum sickness ensue—cutaneous symptoms (i.e., urticaria, maculopapular rash, and erythema multiforme), polyarthralgia, and fever. The onset typically is 7 to 21 days after initiation of penicillin therapy but can occur after use of the antibiotic has been discontinued. Although serum sickness has been associated with the administration of penicillins, it occurs more frequently after administration of cefaclor.
4. Type 4 delayed hypersensitivity reactions involve cellular rather than humoral immunity. On exposure to certain antibiotics, T lymphocytes become sensitized in a major histocompatibility restricted fashion and they mediate mild-to-severe reactions that include contact dermatitis, some maculopapular rashes, fixed drug eruption at sites of previous tinea infections, and toxic epidermal necrolysis. Diagnostic tools to detect an antibiotic that induces a type 4 reaction include the delayed reading (>6 hours) intradermal skin test, patch test, and in vitro lymphocyte transformation test. However, these tests have not been adequately standardized for routine use.[301]

Idiopathic reactions are those for which an immune-mediated mechanism has not been proved, but more recent data suggest that these reactions may represent a type 4 hypersensitivity reaction.[301] Included in this category are the morbilliform exanthems, erythema multiforme, photosensitivity reactions, exfoliative dermatitis, and pruritus. Approximately 4 percent of courses of penicillin and up to 9 percent of courses of ampicillin or amoxicillin therapy are associated with a maculopapular rash. In some of these patients, the rash is a manifestation of a primary viral infection such as infectious mononucleosis, for which the penicillin was prescribed inappropriately.

Identifying patients who will have a significant reaction if penicillin is administered remains difficult. Serologic assays (radioallergosorbent tests) for the detection of IgE antibodies to major and minor penicillin determinants are available but are time-consuming, expensive, and less sensitive than skin testing. Because the immediate reaction is mediated largely by IgE reagin or skin-sensitizing antibody, patients who are likely to respond subsequently with a life-threatening reaction can be identified by the use of intradermal tests with appropriate antigens. However, selecting the most appropriate antigens to be used for skin testing has been problematic because many different antigens may play roles in the allergic reaction. Penicillin is degraded to various clinical products. At least 10 metabolic breakdown products of the penicillin nucleus have been identified. Other potential antigens include macromolecular impurities present in solutions of the drug, high-molecular-weight penicillin polymers found in poorly buffered penicillin solutions standing for prolonged periods, side chains of the various penicillins, and the bacterial enzymes (amidases) used to prepare semisynthetic penicillins. Thus, investigators have had difficulty choosing sensitive and specific antigens to use for skin testing. When these products are used in penicillin skin testing, the predictive value of testing for drug-specific IgE antibodies is high. However, skin testing evaluates IgE-mediated allergy only. For antibiotics other than penicillin it is not clear if the appropriate antigenic determinants are being used, for which a negative test should be interpreted with caution.[128]

The most informative studies of skin test antigens have been those of Levine,[186] who identified two antigens, benzylpenicilloyl poly-L-lysine (PrePen) and a "minor determinant mixture," a preparation of a dilute solution of aqueous crystalline penicillin G that includes metabolic breakdown products. Only the PrePen reagent is available commercially in the United States. The CDC currently recommends the use of benzylpenicilloyl poly-L-lysine and, if available, a freshly prepared mixture of dilute minor determinant precursors, including benzylpenicillin G, benzylpenicilloate, and penicilloyl propylamine, as well as a positive control (histamine) and a negative control (diluent, phenol saline) after a protocol prepared by Beall.[27,316] If the full battery of minor antigens is not available, penicillin G should be used. An epicutaneous (prick) test is performed first. If the patient's history of penicillin allergy is that of a mild reaction, the skin test reagent can be used at full strength; however, if the previous history is suggestive of anaphylaxis, a 1:100 dilution of the reagent should be used for the first prick test, followed by a full-strength test if no reaction with the diluted reagent occurs. If the prick test result is negative, an intradermal test is performed using duplicate 0.02-mL volumes of antigen solutions, and the skin is observed for 20 minutes. A positive result is indicated by a wheal-and-flare reaction in 15 minutes that is more than 2 mm larger than the initial wheal; this result suggests a significant chance that a reaction will occur on subsequent administration of a penicillin. A negative result suggests that a significant allergic reaction will not take place. Although much effort has gone into clinical tests of these antigens, the predictive value of positive and negative results in children remains uncertain. Because of the risk for severe life-threatening reactions when a skin test is performed, having a physician present and resuscitation equipment and medications readily available is prudent.

At present, the physician must rely on the patient's history of an adverse reaction after administration of a penicillin to identify who is likely to be allergic. If the reaction appears to be related to the administration of a penicillin, the drug should be avoided for minor infections. More recent experience suggests that fewer than 10 percent of adults with a history of penicillin allergy have positive skin tests. Of those individuals with negative skin tests, IgE-mediated reactions occur in 4 percent or fewer if these patients receive penicillin, a rate that is similar to that in individuals with no history of penicillin allergy.[301] Because no proved alternative therapies to penicillin are available for treating patients with neurosyphilis, congenital syphilis, or syphilis in pregnancy, the CDC recommends skin testing and desensitization of patients considered to have reacted positively to the skin test antigens.[316] If a life-threatening infection should occur and penicillin is clearly the drug of choice, the physician may choose to administer the drug under carefully controlled conditions after desensitization. All penicillins are cross reactive with regard to sensitization; allergy to any one implies sensitization to all, although cross sensitivity is considerably less than 100 percent.

Cephalosporins

The cephalosporins have a broad range of activity that includes gram-positive cocci, gram-negative enteric bacilli, and anaerobic bacteria. Most cephalosporins are relatively resistant to hydrolysis by β-lactamases produced by *S. aureus*, but many are susceptible to gram-negative β-lactamases. Unlike other antimicrobial agents, this group has a high therapeutic-toxic index. For simplicity, the cephalosporins have been categorized as first-, second-, third-, and fourth-generation agents (Table 235-5), based on the pattern of in vitro activity. Newer generation cephalosporins have been evaluated recently, and in 2010 ceftaroline was approved by the FDA for use in adults with acute skin and soft tissue infections and community-acquired bacterial pneumonia. Ceftobiprole has not been approved for use in the United States, but is available in Canada.

Pharmacokinetics

The cephalosporins are available as parenteral and oral products (Table 235-6). Most of the parenteral drugs can be administered by the intravenous or intramuscular routes. Most of the oral products are absorbed well from the gastrointestinal tract. Esterification of the base compounds of cefuroxime and cefpodoxime is required to enhance gastrointestinal absorption. The presence of food does not alter absorption and, for some antibiotics, even can enhance absorption. Cephalosporins penetrate most tissues and body fluids well, except CSF. The first- and second-generation cephalosporins do not achieve therapeutic CSF concentrations. CSF penetration of third-generation drugs varies but is generally adequate for most major meningeal pathogens, except penicillin-nonsusceptible pneumococci, for which vancomycin is added in the initial empirical regimen.[177] Cefepime, a fourth-generation cephalosporin, reaches adequate CSF concentrations for the treatment of most common invasive pathogens. Because glomerular filtration and tubular secretion are the major modes of excretion, the urinary concentrations achieved are sufficient for the treatment of urinary tract infections. Ceftriaxone has dual excretion by the kidneys and the biliary tract and

[g]Suspension formulation has greater bioavailability than the capsule formulation.
[h]Forty to 75 percent eliminated unchanged in bile.
[i]The half-life is prolonged after intramuscular administration.

achieves high concentrations in urine and bile. The presence of moderate-to-severe renal insufficiency may require adjustment of the dosage or dosing interval for all cephalosporins, except those agents with biliary excretion. Hepatic insufficiency can affect the metabolism of cephalosporins that undergo biliary excretion; however, adjustments in ceftriaxone dosage or dosing interval are required only in the presence of both hepatic and renal insufficiency.

Therapeutic advantages of cephalosporins include concentration-independent bactericidal activity, broad-spectrum antibacterial activity, lack of significant dose-related toxicity, and relative stability against staphylococcal β-lactamases. Certain cautions must be kept in mind when prescribing cephalosporins: none is effective against enterococci, methicillin-resistant staphylococci, *L. monocytogenes*, chlamydial species, and *C. difficile*, and resistance may develop rapidly in closed communities, such as neonatal or pediatric intensive care units, because of inducible chromosomal β-lactamases produced by gram-negative bacteria. The new-generation cephalosporin, ceftaroline, has minimal activity against *Enterococcus faecalis* and no activity against *E. faecium*.[29,288]

First-Generation Cephalosporins

First-generation cephalosporins are effective against gram-positive cocci, including β-lactamase–producing *S. aureus*, and they have variable activity against gram-negative enteric bacilli. Five first-generation cephalosporins currently are available for infants and children: the parenteral drugs cephapirin and cefazolin, the oral products cephalexin and cefadroxil, and cephradine.

Cephalothin is not available in the United States. Because cephapirin is painful in intramuscular injections, the intravenous route is preferred. Cefazolin produces higher concentrations in blood than do the other parenteral first-generation drugs. Cefadroxil can be administered in twice-daily doses because of its longer serum half-life. None of these agents will attain appreciable concentrations in the central nervous system (CNS).

These drugs are of value as alternatives to penicillin for disease caused by *S. aureus*, *S. pyogenes*, and susceptible *S. pneumoniae*, and they are active against some strains of community-acquired gram-negative enteric bacilli such as *E. coli*, *P. mirabilis*, and *Klebsiella pneumoniae*. The three oral preparations have comparable activity in vitro and in vivo. First-generation cephalosporins are valuable in children who have a history of nonanaphylactic allergy to penicillin. These drugs have been used to treat staphylococcal and streptococcal skin and skin structure infections, bone and joint infections, pharyngitis, and uncomplicated community-acquired urinary tract infections caused by susceptible bacteria. A meta-analysis revealed that many first-generation and other-generation cephalosporins (i.e., cephalexin, cefadroxil, cefuroxime, cefprozil, cefdinir, cefixime, cefpodoxime, and ceftibuten) have equivalent or superior bacteriologic and clinical cure rates in contrast to penicillin for treatment of group A streptococcal pharyngotonsillitis.[62] Experts disagree on the significance of the results of this meta-analysis. Cefadroxil is effective for the treatment of streptococcal pharyngitis in a once-daily dosage schedule. Cephalexin has been used for sequential parenteral-oral treatment of staphylococcal osteomyelitis and arthritis occurring after surgical intervention and an initial period of parenteral antibiotic therapy. Cefazolin and cefuroxime are the antibiotics of choice for perioperative prophylaxis in selected surgical procedures.[50] Because first-generation cephalosporins have minimal, if any, activity against *H. influenzae* and *M. catarrhalis* and inadequate activity against penicillin-resistant *S. pneumoniae*, they should not be used for empirical treatment of respiratory tract infections. First-generation cephalosporins should not be used for empirical therapy of suspected severe gram-negative health care–associated infections; a third- or fourth-generation cephalosporin in combination with an aminoglycoside, or other classes of antibiotics, should be selected for this purpose. The safety and efficacy of cefaclor, cefazolin or cephalexin, and cephapirin have not been established for infants younger than 1 and 3 months of age, respectively.

Second-Generation Cephalosporins

The second-generation cephalosporins that are approved for use in children consist of two parenteral drugs (cefamandole and cefuroxime) and three oral preparations (cefaclor, cefuroxime axetil, and cefprozil). Also classified with the second-generation cephalosporins are the cephamycins, of which only one, cefoxitin, is approved for use in children. When compared with the first-generation cephalosporins, the second-generation agents have similar or somewhat less activity against gram-positive cocci but better activity against *H. influenzae*, *M. catarrhalis*, *N. meningitidis*, *N. gonorrhoeae*, and some members of the Enterobacteriaceae. The cephamycins are more active than first- or other second-generation cephalosporins against gram-negative enteric bacteria and *B. fragilis*, but they have poor activity against gram-positive cocci.

Cefaclor. Cefaclor is more active than cephalexin against *H. influenzae*, *M. catarrhalis*, *E. coli*, and *P. mirabilis* and has activity against staphylococci similar to that of cephalexin. Cefaclor is an unstable compound and is destroyed within 2 hours in human plasma. It is susceptible in vitro to hydrolysis by the β-lactamases produced by approximately 14 percent of *H. influenzae* and 90 percent of *M. catarrhalis* isolates; presumed rates of resistance of *H. influenzae* are considerably higher when pharmacokinetic and pharmacodynamic parameters are taken into account.[150] Although cefaclor is effective therapy for susceptible bacteria causing otitis media, sinusitis, and mild-to-moderate cases of pneumonia, it is not the preferred empirical agent for these indications because it is not effective against penicillin-nonsusceptible strains of *S. pneumoniae*. The rare but potential risk for serum sickness, as well as the poor stability of this drug to some β-lactamases, has limited its use. The safety and efficacy of cefaclor have not been established for infants younger than 1 month of age, although the drug has been used successfully to treat neonatal otitis media.

Cefamandole. Cefamandole is active against gram-positive cocci, including β-lactamase–producing *S. aureus*, and some gram-negative enteric bacteria, and it was the first cephalosporin to be effective for infections caused by *H. influenzae*, including β-lactamase–producing strains. However, this agent is no longer available in the United States. Before the development of cefuroxime, cefamandole was used for respiratory tract, skin, and soft tissue infections in infants and children.[18] Once cefuroxime was approved for use, cefamandole seldom was used because, although its spectrum of activity was comparable with that of cefuroxime, some of its pharmacologic features made it less favorable. Cefamandole does not penetrate the CSF well, and because it contains a methylthiotetrazole side chain, altered hemostasis may occur. Clinical and microbiologic failure in cases of meningitis caused by *H. influenzae* (despite in vitro susceptibility and evidence of CSF penetration) has limited the use of cefamandole to disease in which the development of sepsis is not a concern. The safety and efficacy of this agent have not been established for infants younger than 1 month of age.

Cefoxitin. Cefoxitin has excellent activity against anaerobic organisms and is the most active cephalosporin against *B. fragilis*.[31] It has selective activity against gram-negative enteric bacilli, but *Enterobacter* or *Pseudomonas* spp. are inherently resistant. Cefoxitin is resistant to hydrolysis by the β-lactamases produced by gram-positive bacteria and some of the gram-negative β-lactamases. Because it is a potent inducer of Bush group 1 chromosomal β-lactamases, its indiscriminate use should be avoided. Cefoxitin has been shown to be effective for

infections involving facultative gram-negative bacilli and anaerobes, such as intra-abdominal, pelvic, and gynecologic infections. When combined with doxycycline, cefoxitin is effective for the treatment of pelvic inflammatory disease.[316] The use of β-lactam and β-lactamase inhibitor combinations or metronidazole, rather than cefoxitin, should be considered for empirical treatment of patients with life-threatening anaerobic infections because as many as 25 percent of *B. fragilis* strains can be resistant to cefoxitin.[5] Higher doses of cefoxitin have been associated with an increased incidence of eosinophilia and elevated aspartate aminotransferase (AST) concentration. A diminished zone of inhibition in cefoxitin disk diffusion assays are useful in the clinical microbiology laboratory to detect inducible or constitutive (stably derepressed) AmpC Bush group 1 β-lactamase production among strains of *Citrobacter*, *Enterobacter*, *E. coli*, *Klebsiella*, *Morganella*, *Providencia*, *Pseudomonas*, and *Serratia*. Identification of this phenotype in vitro is important because these strains have high-level resistance to many classes of β-lactam antibiotics that may not be detected by standard susceptibility assays. Fourth-generation cephalosporins and carbapenems are potentially effective antimicrobial agents for these multidrug-resistant pathogens.[158]

Cefprozil. Cefprozil has a structure similar to that of the first-generation cephalosporin cefadroxil. It is more active than the oral first-generation agents against *S. pyogenes*, *S. pneumoniae*, *Neisseria* spp., *H. influenzae*, *M. catarrhalis*, *E. coli*, *P. mirabilis*, *Klebsiella*, and, to a lesser extent, staphylococci. This drug is hydrolyzed by the β-lactamases produced by approximately 11 percent of *H. influenzae* and 91 percent of *M. catarrhalis* isolates; rates of resistance of *H. influenzae* are likely considerably higher when pharmacokinetic and pharmacodynamic parameters are taken into account.[150] The rate of resistance among *S. pneumoniae* isolates in the United States is approximately 20 percent.[156] Because of its relatively long serum half-life, cefprozil can be administered twice daily. Cefprozil is comparable to penicillin, cefaclor, and erythromycin in the treatment of pharyngitis,[206] and it is equivalent or superior to cefaclor and erythromycin in the treatment of mild-to-moderate skin and skin structure infections.[233] Cefprozil is approved for the treatment of acute otitis media, mild lower respiratory tract infections, acute sinusitis, and skin and skin structure infections. However, it is not the preferred antibiotic for these indications because it is unlikely to be effective in children with penicillin-nonsusceptible *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis*, on the basis of unfavorable pharmacodynamic parameters.[307] Cefprozil is safe and effective as part of a parenteral-oral antibiotic regimen for the treatment of suppurative skeletal infections in children.[308] The safety and efficacy of cefprozil have not been established for infants younger than 6 months of age.

Cefuroxime. In contrast to first-generation cephalosporins, this parenteral second-generation cephalosporin is slightly less active against staphylococci but is more active against group A streptococci and pneumococci. Cefuroxime has excellent activity against many members of the Enterobacteriaceae.[230] Its stability to β-lactamases is greater than that of first-generation agents, and it is the only first- or second-generation antibiotic that achieves substantial CSF concentrations. However, cefuroxime is not recommended for treatment of proved or suspected bacterial meningitis because of suboptimal CSF pharmacologic characteristics, particularly in the context of infections caused by *H. influenzae* or nonsusceptible *S. pneumoniae*, for which third-generation cephalosporins (cefotaxime and ceftriaxone) are indicated.[280] Cefuroxime has been approved for the treatment of skin and skin structure infections, lower respiratory tract infections, bone and joint infections, uncomplicated gonorrhea, and uncomplicated urinary tract infections caused by susceptible bacteria. Cefuroxime is most useful for the treatment of infections sufficiently severe to warrant parenteral therapy, in which susceptible *S. aureus*, *S. pneumoniae*, *S. pyogenes*, encapsulated or nonencapsulated *H. influenzae*, and *M. catarrhalis* are probable pathogens, such as suppurative arthritis, orbital cellulitis, or severe pneumonia. Cefuroxime offers the advantage of single-drug therapy for these diseases. The safety and efficacy of cefuroxime have not been established for infants younger than 3 months of age.

Cefuroxime Axetil. Cefuroxime axetil is an oral form of cefuroxime with a similar spectrum of activity. It is an ester prodrug of cefuroxime that is metabolized to the active drug by intestinal esterases. Oral absorption is increased by the presence of food. When crushed, the tablet has a bitter taste that renders it unpalatable. The suspension has an unpleasant flavor that makes it difficult for some children to tolerate and therefore may limit adherence. The drug may be considered a suitable alternative to amoxicillin for the treatment of otitis media[10] and sinusitis when coverage must include β-lactamase–producing bacteria. Cefuroxime axetil has limited activity against penicillin-nonsusceptible pneumococci and *M. catarrhalis*, of which approximately 22 percent and 50 percent, respectively, of isolates are resistant.[150,156] This agent has been approved for the treatment of uncomplicated urinary tract infection, skin and soft tissue infection, acute bacterial maxillary sinusitis, and lower respiratory tract infection caused by susceptible bacteria. Cefuroxime axetil is an effective alternative to doxycycline and amoxicillin for the treatment of early Lyme disease.[317] The safety and efficacy of cefuroxime axetil have not been established for infants younger than 3 months of age.

Third-Generation Cephalosporins

Third-generation cephalosporins approved for use in children include the parenteral agents cefotaxime, ceftizoxime, ceftriaxone, and ceftazidime and the oral agents cefixime, cefpodoxime proxetil, ceftibuten, cefdinir, and cefditoren pivoxil. Third- and fourth-generation cephalosporins are the most potent cephalosporins against gram-negative enteric bacteria.[160] Most of them have excellent activity against *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, *N. meningitidis*, group A streptococci, and penicillin-susceptible pneumococci but relatively poor

activity against staphylococci. Ceftazidime is the only agent with activity against *P. aeruginosa*. A serious global health concern has emerged because members of the Enterobacteriaceae have developed increased resistance to third-generation cephalosporins on the basis of plasmid-mediated production of extended-spectrum and AmpC β-lactamases.[245] The parenteral cephalosporins provide high concentrations of drug in serum and adequate concentrations in CSF. Third-generation cephalosporins and aminoglycosides are synergistic in vitro against certain susceptible and resistant strains of *P. aeruginosa* as well as *Serratia marcescens* and other Enterobacteriaceae, including *Enterobacter cloacae*, *E. coli*, *K. pneumoniae*, and *P. mirabilis*.

In 2010, the CLSI released revised breakpoints for Enterobacteriaceae for third-generation cephalosporins and the first-generation cefazolin. The current MIC breakpoints in micrograms per milliliter are 1 and less for susceptible, 2 for intermediate, and 4 and greater for resistant organisms for cefazolin, cefotaxime, ceftizoxime, and ceftriaxone. For ceftazidime the MIC breakpoints are 4 and less, 8, and 16 or greater for susceptible, intermediate, and resistant organisms, respectively. Similarly, breakpoints for aztreonam (a monobactam) were revised. The revised breakpoints seek to eliminate the need to perform ESBL screen to direct patient care.[314]

Cefotaxime. Cefotaxime has excellent activity against group A streptococci, susceptible pneumococci, *H. influenzae*, *N. meningitidis*, and *N. gonorrhoeae*. Because cefotaxime can be hydrolyzed by AmpC Bush group 1–inducible chromosomal β-lactamases and by extended-spectrum β-lactamases (ESBLs), it is not active against strains of Enterobacteriaceae that produce these β-lactamases. Cefotaxime is metabolized in the liver to desacetyl cefotaxime, a less active metabolite that may act synergistically with cefotaxime. Although it is metabolized in the liver, cefotaxime is excreted by the kidneys. High serum, tissue, and CSF concentrations of cefotaxime can be achieved at the recommended dosages. The rapid development of resistance by colonizing gram-negative enteric bacilli when cefotaxime was used extensively for initial treatment of neonatal sepsis raised concern that extensive use of newer cephalosporins in the nursery or intensive care units could lead to more rapid emergence of drug-resistant bacteria than had been identified with the traditional regimens of a penicillin and an aminoglycoside. Because of its broad spectrum of activity against many of the common pathogens causing pediatric infections, cefotaxime is used widely for inpatient treatment of lower respiratory tract infections, urinary tract infections, sepsis, intra-abdominal infections, bone and joint infections, and meningitis or ventriculitis caused by susceptible organisms. Studies in neonates have raised concern that when cefotaxime is used routinely as part of an empirical regimen for neonatal sepsis, colonizing gram-negative enteric bacilli can rapidly develop resistance and certain neonates have adverse outcomes.[70,89] Therefore, it is prudent to reserve cefotaxime for appropriate clinical and microbiologic indications. In 2003, the CLSI published new breakpoints for defining the susceptibility of *S. pneumoniae* isolates to cefotaxime and ceftriaxone. The former breakpoints were based on attainable concentrations of these antibiotics in CSF and the level at which it was presumed that meningitis treatment failed because of elevated MICs. According to the former criteria, susceptible, intermediate, and resistant MIC breakpoints for cefotaxime and ceftriaxone were 0.5 μg/mL or less, 1 μg/mL, and 2 μg/mL or more, respectively, for pneumococci. Based on the newer criteria, the original breakpoints should be used for isolates from CSF in patients with suspected meningitis, but isolates causing nonmeningeal syndromes have breakpoints of 1 μg/mL or less, 2 μg/mL, and 4 μg/mL or more, respectively.[64]

Ceftizoxime. Ceftizoxime is a parenteral agent with a spectrum of activity similar to that of cefotaxime. Its safety and efficacy have not been established for infants younger than 6 months of age, and it rarely is used in pediatrics.

Ceftriaxone. The antibacterial spectrum of ceftriaxone is similar to that of cefotaxime, with activity against β-hemolytic streptococci (including groups A, B, C, F, and G), susceptible pneumococci, *H. influenzae*, *M. catarrhalis*, *Neisseria* spp., and many members of the Enterobacteriaceae. Surveillance data from pediatric patients in the United States revealed that no significant resistance has been reported against ceftriaxone among oxacillin-susceptible strains of *S. aureus*.[160] Nonetheless, this drug should not be used as empirical monotherapy for severe infections presumed to be caused by staphylococci, because it has minimal activity against MRSA and its efficacy for treatment of susceptible strains has not been established in children. Ceftriaxone is not active against most strains of *Pseudomonas*. It differs from cefotaxime in pharmacokinetic properties. Ceftriaxone undergoes extensive protein binding and has a long serum half-life. Because of its broad spectrum of activity against many of the pathogens that commonly cause sepsis, meningitis, and respiratory tract infections in older infants and children, along with its unique pharmacokinetic features, ceftriaxone has been used excessively for outpatient management of febrile infants and young children being evaluated for possible systemic bacterial infection. Single-dose therapy was approved for the treatment of acute otitis media in 1997; a 3-day regimen is recommended as alternative therapy for patients with refractory cases.[10,185]

Ceftriaxone is effective for various sexually transmitted diseases (STDs), including chancroid, proctitis, epididymitis (in combination with doxycycline), and different forms of gonococcal disease (e.g., neonatal ophthalmia); uncomplicated urethral, endocervical, rectal, or pharyngeal gonorrhea (in combination with doxycycline for treatment of possible coexisting chlamydial infection); and disseminated gonococcal infection, meningitis, or endocarditis.[316] Short-course ceftriaxone therapy for typhoid fever in children is comparable in effectiveness to chloramphenicol therapy.[216] However, duration of ceftriaxone therapy longer than 5 days has been associated with fewer confirmed bacteriologic relapses.[294] Ceftriaxone (or cefotaxime) is recommended for treatment of

acute Lyme disease with advanced heart block (14 to 21 days) or meningitis (14 to 28 days).[317] Although third-generation cephalosporins have been used for empirical treatment of health care–associated respiratory, wound, intra-abdominal, and urinary tract infections caused by gram-negative bacteria, administering an aminoglycoside instead of or in addition to a third-generation cephalosporin often is prudent because of the risk for encountering plasmid-mediated, ESBL resistance, or inducing the expression of chromosomally mediated AmpC Bush group 1 β-lactamases.

For infections requiring prolonged therapy (e.g., suppurative arthritis, osteomyelitis, and brain abscess) and caused by susceptible organisms, ceftriaxone therapy is cost-effective for use outside of the hospital. Once the acute signs of disease have diminished and the child remains in the hospital for only parenteral therapy, discharge and once-daily administration of ceftriaxone in the home or clinic can be considered.

Because of its extensive protein binding, ceftriaxone can displace bilirubin from albumin-binding sites, with the potential risk for inducing kernicterus, although to date this adverse clinical effect has not been reported. Cefotaxime is administered to neonates more often than ceftriaxone because considerably more information is available on its safety and pharmacokinetics. Ceftriaxone is excreted and concentrated in bile. Gallbladder "sludge," diagnosed by abdominal sonography (and not identifiable by other radiographic techniques), has been demonstrated in some patients who received ceftriaxone. The material appears to be a calcium–ceftriaxone complex and resolves on cessation of the drug. Most patients with ceftriaxone-associated sludge are asymptomatic, but occasionally patients have symptoms of gallbladder disease and incidents of acute cholecystitis have been reported in a few children.

Ceftazidime. In contrast to cefotaxime and ceftriaxone, ceftazidime has poor antibacterial activity against *S. aureus*, is less active against penicillin-susceptible *S. pneumoniae*, and is slightly less active against group A streptococci, but it is more active against *P. aeruginosa*. On a weight basis, ceftazidime is the most effective of all β-lactam antimicrobial agents in vitro against *P. aeruginosa*. It frequently is active in vitro against *P. aeruginosa* strains that are resistant to antipseudomonal penicillins. Resistance to ceftazidime can develop in gram-negative bacteria by the production of ESBLs or because of decreased bacterial cell permeability, as seen with *P. aeruginosa*, *Acinetobacter*, and some *Serratia* strains. Ceftazidime is indicated for use in the following circumstances: infections suspected to be caused by *Pseudomonas*, including acute exacerbations of chronic pulmonary infections in patients with cystic fibrosis, chronic suppurative otitis media, or malignant otitis externa; thermal injuries, puncture wound infections of the foot, and complicated health care–associated infections; and febrile illnesses in neutropenic patients with cancer or other immunocompromised individuals.

Cefixime. Cefixime has a vinyl group instead of a chlorine atom at position 3 of the cephem nucleus and an aminothiazole oxime group, rather than a phenyl glycine side chain. These biochemical changes result in potent gram-negative activity. Cefixime was introduced in 1989 as an oral third-generation cephalosporin with a broad spectrum of activity, including activity against group A streptococci, *H. influenzae*, *M. catarrhalis*, susceptible *S. pneumoniae*, and many members of the Enterobacteriaceae, including *Shigella*, *Salmonella*, *E. coli*, *Klebsiella*, and *P. mirabilis*.[24] Cefixime, like ceftibuten, is distinguished from other extended-spectrum oral cephalosporins by its lack of activity against *S. aureus*. It also is inactive against *Citrobacter freundii*, *Enterobacter*, *P. aeruginosa*, and *Serratia*. Although cefixime has in vitro activity against penicillin-susceptible pneumococci, lower bacteriologic cure rates occurred with cefixime than with amoxicillin when cefixime was used to treat children with pneumococcal acute otitis media.[142] Cefixime is resistant to degradation by certain β-lactamases. Administration of cefixime is facilitated by once-daily dosing,[100] pleasant taste, and stability of the suspension at room temperature. Cefixime is effective therapy for uncomplicated urinary tract infections caused by *E. coli* or *P. mirabilis*, for shigellosis, and for acute otitis media or sinusitis caused by *H. influenzae* or *M. catarrhalis*.[36] Some specialists use cefixime to treat uncomplicated gonococcal infections in children because the drug can be administered orally; however, no reports have been published concerning the safety or effectiveness of cefixime used for this purpose.[316] Clinical studies indicate that the rate of laboratory-confirmed eradication of *Shigella sonnei* in an epidemic setting is higher with a 5-day than with a 2-day cefixime regimen,[204] cefixime alone is equally effective as sequential therapy with intravenous and oral antibiotics in selected febrile infants with urinary tract infections,[34,138] and a 14-day cefixime regimen for treatment of multidrug-resistant *Salmonella typhi* septicemia in children has efficacy comparable to that of a 5-day course of ceftriaxone therapy.[119] Cefixime is not recommended for the treatment of infections frequently caused by staphylococci, such as skin or soft tissue infections, and it is not the most effective agent for the treatment of pneumococcal infections. The safety and efficacy of cefixime have not been established for infants younger than 1 month of age. Wyeth discontinued manufacturing cefixime in 2002, but the drug was reintroduced in 2004 as a generic formulation (Lupin Pharmaceuticals).

Cefpodoxime Proxetil. The antibacterial activity of cefpodoxime proxetil is similar to that of cefixime, with the exception of improved activity against staphylococci. Cefpodoxime is active against group A streptococci; susceptible pneumococci; β-lactamase–producing strains of *N. gonorrhoeae*, *H. influenzae*, and *M. catarrhalis;* oxacillin-susceptible *S. aureus;* and many members of the Enterobacteriaceae. It is not active against *Enterobacter*, *Pseudomonas*, *Serratia*, or *Morganella*. Cefpodoxime proxetil, the ester prodrug of cefpodoxime, is cleaved by intestinal esterases to the active drug. Oral absorption is increased by the presence of food. Because of its longer serum half-life, cefpodoxime proxetil can be administered in twice-daily dosing intervals. Cefpodoxime is hydrolyzed by some ESBLs. The unfavorable

palatability of cefpodoxime proxetil may adversely affect adherence.[289]

Treatment of group A streptococcal pharyngitis with a 5-day cefpodoxime proxetil regimen is equivalent to therapy with penicillin V and has been approved for this indication by the FDA.[82] A 5-day regimen is approved for the treatment of acute otitis media based on clinical outcomes that are comparable or superior to those with therapy with amoxicillin-clavulanate, cefaclor, or cefixime.[72] Cefpodoxime is not likely to be effective for the treatment of acute otitis media caused by penicillin-nonsusceptible pneumococci because of its unfavorable pharmacodynamic parameters.[312] It also has been approved for outpatient treatment of community-acquired respiratory tract infections, uncomplicated urinary tract infections, and mild skin and skin structure infections. The safety and efficacy of cefpodoxime proxetil have not been established for infants younger than 5 months of age.

Ceftibuten. Ceftibuten was approved by the FDA for pediatric use in 1995. The primary active component is formulated as a *cis*-isomer that is converted in serum to the less active *trans*-isomer. The chemical structure and spectrum of antimicrobial activity are similar to those of cefixime. Ceftibuten, like cefixime, is distinguished from other extended-spectrum oral cephalosporins by its lack of activity against *S. aureus*. Its antimicrobial activity against groups A, C, F, and G β-hemolytic streptococci is good, whereas its activity against groups B and D, as well as viridans streptococci, is poor. Ceftibuten exhibits MICs for penicillin-susceptible pneumococci in the susceptible range, whereas penicillin-nonsusceptible strains are ceftibuten-resistant. In contrast to other oral cephalosporins, ceftibuten is the most stable to hydrolysis by β-lactamases produced by Neisseriaceae, *Moraxella*, *Haemophilus*, and Enterobacteriaceae, including most strains of *E. coli* and *K. pneumoniae* that produce Ambler class A plasmid-mediated, ESBLs of the TEM, SHV, and OXA types. Ceftibuten is variably active against strains of *Citrobacter*, *Serratia*, and *Morganella*, but it is inactive against *Acinetobacter*, *Pseudomonas*, *Enterobacter*, *Bordetella*, and anaerobic species. It is also a weak inducer of AmpC Bush group 1 β-lactamases produced by *S. marcescens*, *E. cloacae*, and *Enterobacter aerogenes*.[129]

Ceftibuten has excellent bioavailability and a favorable pharmacokinetic profile that facilitates a once-daily dosing schedule.[23] Treatment regimens of 10 days have been approved for streptococcal tonsillopharyngitis and acute otitis media caused by *H. influenzae*, *M. catarrhalis*, or *S. pyogenes* because of superior clinical and microbiologic efficacy data for ceftibuten in comparison with penicillin V in children with streptococcal tonsillopharyngitis[248] and comparable clinical efficacy data for ceftibuten versus amoxicillin, amoxicillin-clavulanate, cefaclor, and cefprozil for the treatment of children with clinically defined acute otitis media with or without effusion. However, cumulative data from clinical trials indicate that microbiologic cure rates of pneumococcal otitis media are lower for ceftibuten than for comparable antimicrobial agents.[129] Because of the increasing prevalence of nonsusceptible *S. pneumoniae* isolates, ceftibuten has almost no place in the treatment of acute otitis media, especially in young or otherwise at-risk infants and children.

Ceftibuten also should be considered as alternative therapy for sinusitis caused by susceptible organisms. Although not approved for this indication, ceftibuten achieved clinical success equivalent to and bacterial eradication superior to those reported with trimethoprim-sulfamethoxazsole in the treatment of complicated or recurrent urinary tract infections in children.[22] Adverse reactions to ceftibuten, which are limited mainly to the gastrointestinal tract, occur in approximately 10 percent of children, a rate similar to comparable oral β-lactam antibiotics. The safety and efficacy of ceftibuten have not been established for infants younger than 6 months of age.

Cefdinir. Cefdinir was approved in 1999 for the treatment of acute otitis media in children. It has a broad spectrum of in vitro antimicrobial activity, favorable pharmacokinetics, a convenient once-daily or twice-daily dosage schedule, superior palatability, a low rate of adverse events, and proved clinical efficacy against common childhood pathogens.[140,174] In contrast to cephalexin, cefaclor, cefuroxime, cefixime, and cefpodoxime, cefdinir has equivalent or superior MICs for groups A, B, C, F, and G streptococci, viridans streptococci, and oxacillin-susceptible staphylococci. Its in vitro activity against penicillin-susceptible and penicillin-nonsusceptible strains of *S. pneumoniae* is equivalent to that of cefuroxime and cefpodoxime but superior to that of other oral cephalosporins. Cefixime and cefpodoxime have superior activity against *H. influenzae* (including β-lactamase–producing strains), whereas cefdinir and cefuroxime have comparable activity against this pathogen. The activity of cefdinir against *M. catarrhalis* is similar to that of cefixime, cefpodoxime, and cefuroxime but superior to that of earlier-generation cephalosporins. Cefdinir is stable to hydrolysis by many common Enterobacteriaceae-produced β-lactamases. However, activity against these pathogens is variable. Cefdinir is inactive against strains of enterococci, methicillin-resistant staphylococci, *Legionella*, *Listeria*, *Acinetobacter*, *Citrobacter*, *Enterobacter*, *P. aeruginosa*, *Serratia*, *Stenotrophomonas*, and most anaerobes.[130]

Based on comparative clinical and microbiologic efficacy trials, administration of cefdinir should be considered for children with (1) acute bacterial otitis media caused by β-lactamase–positive or β-lactamase–negative strains of *H. influenzae* and *M. catarrhalis* or penicillin-susceptible strains of *S. pneumoniae* as either a 5- or 10-day regimen; cefdinir has efficacy equivalent to that of cefuroxime and cefpodoxime but superior palatability and therefore should be considered as an alternative to other second-line regimens; however, use of amoxicillin-clavulanate or three single daily doses of parenteral ceftriaxone is recommended if penicillin-nonsusceptible pneumococci are suspected or proved[10,12,174]; (2) group A streptococcal tonsillopharyngitis in 5- or 10-day dosage schedules; (3) acute maxillary sinusitis caused by susceptible organisms; and (4) uncomplicated skin and skin structure infections caused by oxacillin-susceptible

S. aureus or group A streptococci.[159] Although cefdinir is not approved for treatment of urinary tract infections, microbiologic data support its potential utility for community-acquired uncomplicated urinary infections.[43] The safety and efficacy of cefdinir have not been established for infants younger than 6 months of age.

Cefditoren Pivoxil. Cefditoren pivoxil was approved by the FDA in 2002 for oral treatment of acute exacerbations of chronic bronchitis, pharyngitis, tonsillitis, and uncomplicated skin and soft tissue infections in adults and adolescents 12 years of age and older. Cefditoren is similar to cefdinir and cefpodoxime in its antibacterial activity. It is stable to hydrolysis by many common Enterobacteriaceae-produced β-lactamases. Cefditoren has the greatest in vitro antimicrobial activity of all oral cephalosporins against *S. pneumoniae*. The inactive metabolite pivalate is eliminated by the kidneys in combination with carnitine as pivaloylcarnitine. Although cefditoren transiently decreases serum concentrations of carnitine, the clinical significance of this is not clear, but no adverse effects have been reported.[205]

Fourth-Generation Cephalosporins

Cefepime. Cefepime, the prototypic agent of this class of antibiotics, was approved by the FDA in 1996. It is distinguished from other cephalosporins by the rapid penetration of outer-membrane porins into the periplasmic space of gram-negative bacteria, facilitated by its net neutral charge; enhanced stability against hydrolysis by inducible or constitutively expressed chromosomally mediated AmpC Bush group 1 β-lactamases and Ambler class A plasmid-mediated SHV- and TEM-type ESBLs; and increased binding affinity to multiple PBPs. These factors contribute to cefepime's expanded spectrum of activity and improved efficacy against gram-negative pathogens in contrast to third-generation cephalosporins.

The in vitro activity of cefepime encompasses a broad range of gram-positive and gram-negative organisms, including oxacillin-susceptible staphylococci; approximately 75 percent of penicillin-resistant strains of *S. pneumoniae;* viridans streptococci; most strains of Enterobacteriaceae, including, most notably, ESBL-producing strains of *E. coli* and *K. pneumoniae;* and AmpC-mediated resistant *Enterobacter* spp., and *Citrobacter* spp., as well as approximately 90 percent of *P. aeruginosa* isolates. Furthermore, bacteria in which resistance to third-generation cephalosporins develops by means of single-step mutations usually remain susceptible to cefepime. Clinical and laboratory data also indicate that selection of cefepime resistance, specifically among *Enterobacter* spp., and *P. aeruginosa*, is rare. As with other cephalosporins, cefepime is inactive against enterococci, methicillin-resistant staphylococci, *S. maltophilia*, and many anaerobic organisms.[160,170]

Cefepime is indicated for the parenteral treatment of lower respiratory tract, urinary tract, skin and skin structure, and intra-abdominal (in combination with anaerobic antibacterial agents) infections, as well as for empirical monotherapy in pediatric patients with cancer who have fever and neutropenia, for whom cefepime has been shown to be as effective as meropenem, piperacillin-tazobactam, or ceftazidime with or without an aminoglycoside. In comparative clinical and microbiologic efficacy trials, cefepime as a single antibacterial agent was equivalent to third-generation cephalosporins for the most common childhood pathogens. In addition, cefepime is as safe and well tolerated, as are other cephalosporin antibiotics.[47,223,279]

Cefepime should be reserved for complicated community-acquired, health care–associated, or polymicrobial infections, penicillin-resistant and third-generation cephalosporin–resistant pathogens, and patients with cystic fibrosis and *P. aeruginosa* lung infections. Cefepime concentrations in CSF reach approximately 3 to 6 μg/mL (9% of the peak plasma concentration) in children with bacterial meningitis. Therefore, achievable CSF concentrations exceed the MICs of common CNS pathogens by at least 10-fold, except for penicillin- and cephalosporin-nonsusceptible *S. pneumoniae*.[39] Currently, data are insufficient to recommend cefepime as single-agent therapy for meningitis. The safety and efficacy of cefepime have not been established for neonates, but data extrapolated from pharmacokinetic studies among preterm and term infants support a dose of 30 mg/kg every 12 hours for infants younger than 14 days of age, regardless of gestational age. This dosage should provide antibiotic exposure equivalent to or greater than the approved dose of 50 mg/kg every 8 to 12 hours in older infants and children.[61]

Fifth-Generation Cephalosporins

Ceftaroline. Ceftaroline fosamil is a recently approved broad-spectrum cephalosporin for the treatment of acute bacterial skin and skin structure infections and community-acquired pneumonia in adults. It received FDA approval in 2010. Ceftaroline has high affinity for PBPs 1, 2, and 3 for methicillin-susceptible strains of *S. aureus* (MSSA). It also contains a side chain with alkoxyimino group in the C7 acyl moiety that provides in vitro activity for MRSA with high affinity for the PBP2a and another side chain with a 2-thiazolythio spacer group modification that optimizes the anti–MRSA activity.[288] Ceftaroline also retains activity against isolates with reduced susceptibility to vancomycin (heterogeneous glycopeptide-intermediate *S. aureus* [hGISA], GISA, and glycopeptide-resistant *S. aureus* GRSA) or linezolid.[29,288] This antibiotic has in vitro activity against gram-positive organisms, including *S. aureus*, both MSSA and MRSA; coagulase-negative staphylococci; group A and group B β-hemolytic streptococci; and *S. pneumoniae*, including multidrug-resistant strains and modest activity against *E. faecalis*. Ceftaroline has no activity against *E. faecium* (MIC_{90} >1632 μg/mL). It has activity against penicillin-nonsusceptible viridans group streptococci. Ceftaroline is active against non-ESBL enteric gram-negative organisms, including *E. coli* and *K. pneumoniae*, respiratory gram-negative organisms (including *M. catarrhalis* and *H. influenzae* and β-lactamase–positive strains), and

N. gonorrhoeae. It has limited activity against nonfermenting gram-negative organisms, including *P. aeruginosa* and *A. baumannii* (with MIC >16 mg/L for both). Ceftaroline can induce expression of AmpC β-lactamases in a degree similar to that of ceftriaxone and cefotaxime based on in vitro induction assays.[288]

Ceftaroline fosamil is a prodrug that is converted into its active form by plasma phosphatases. It is administered only in the intravenous form, infused over 60 minutes in a twice-daily regimen. It is eliminated primarily by renal excretion with an approximate half-life of 3 hours. Dosage adjustment is required for moderate renal impairment and for patients receiving hemodialysis. Protein binding seems to be minimal (ranging from 1% to 19% at different concentrations).

Phase II and III clinical trials evaluated the effectivity of ceftaroline in contrast to the combination vancomycin and aztreonam for the treatment of complicated skin and skin structure infections, with similar clinical cure rates; the primary outcome was noninferiority of clinical cure rate. For patients with microbiologic data, eradication rates were also similar. The drug was well tolerated, and no safety concerns were reported. The most common adverse effects were diarrhea, nausea, headache, and insomnia. It may cause changes in urine color or smell. Ceftaroline did not cause QTc interval prolongation.[78,291]

Results from two randomized, double-blind, multicenter, phase III trials showed similar cure rates for patients with community-acquired pneumonia comparing ceftaroline and ceftriaxone (± clarithromycin).[104,196]

Adverse Effects

The cephalosporins, like the penicillins, are safe for children and have almost no dose-related toxicity. The most common reactions are local, including pain at the injection site or thrombophlebitis with parenteral administration and mild gastrointestinal complaints with oral dosing. Hypersensitivity reactions occur in approximately 1 to 3 percent of treatment courses and include morbilliform rash, urticaria, and pruritus. Drug fever has been associated with the administration of cephalosporins. Nonspecific antibiotic-associated diarrhea and, less commonly, *C. difficile* toxin–mediated colitis can occur after use of cephalosporin.

Other adverse effects are rare, and some are unique to one or a few cephalosporins. Physicians should be alert for uncommon reactions, including reversible neutropenia, which can occur after prolonged use of high-dosage cephalosporins, Coombs-positive hemolytic anemia, and bleeding. Altered hemostasis because of hypoprothrombinemia can result when using any cephalosporin that contains a methylthiotetrazole side chain (cefamandole, cefotetan, and moxalactam). These agents act as competitive inhibitors of vitamin K–dependent carboxylase, which converts clotting factors II, VII, IX, and X to their active forms. Gallbladder sludging, biliary pseudolithiasis, and symptomatic obstructive biliary disease rarely have been associated with the administration of ceftriaxone.[323]

The cephalosporins may produce allergic reactions similar to those caused by the penicillins. Cross sensitization exists among the cephalosporins, and allergy to one cephalosporin implies allergy to all. Various degrees of immunologic cross reaction of penicillins and cephalosporins have been demonstrated in vitro and in animal models.[244] Previously quoted studies suggest that the frequency of allergic reactions to cephalosporins ranges from 5.4 to 16.5 percent in adult patients with a history of penicillin allergy and 1.0 to 2.5 percent in those without such a history. The incidence of hypersensitivity to unrelated drugs is increased in some patients who are allergic to penicillin, a finding suggesting that excipients in antibiotic preparations may be responsible for these reactions.[276] Most patients who are thought to be allergic to penicillin receive cephalosporins without adverse reaction. Data indicate that the risk for an allergic reaction to a cephalosporin challenge among penicillin-allergic subjects with positive skin test responses is 4 percent. Therefore, the following options are available for individuals with positive skin test responses for penicillin hypersensitivity: administration of an alternative non–β-lactam antibiotic, administration of a cephalosporin by graded challenge, or desensitization to the cephalosporin. Individuals with a history of penicillin allergy who have negative penicillin skin test responses may receive cephalosporins because they are at no higher risk than the general population for experiencing allergic reactions.[190] In the absence of penicillin skin testing, a cephalosporin may be used with caution as an alternative to penicillin in children who have an ambiguous history of rash; however, cephalosporins should be avoided in patients with a known immediate or accelerated reaction to a penicillin. Currently, skin testing to evaluate for cephalosporin hypersensitivity is not possible because the potential cephalosporin haptens are unknown, and no standardized antigen exists.

Some products may cause unexpected reactions, such as bile sludge attributed to ceftriaxone and serum sickness–like disease described with cefaclor. A generalized pruritic rash, similar to erythema multiforme, developed in some children treated with cefaclor, along with fever, purpura, and arthritis with pain and swelling in the knees and ankles. The signs appeared 5 to 19 days after the start of therapy and generally disappeared within 4 to 5 days after discontinuing use of the drug. The children had no previous history of allergy to a penicillin or cephalosporin.[222] Levine[187] compared adverse reactions in children who received cefaclor (1017 patients and 2513 courses) or amoxicillin (1009 patients and 2358 courses). Serum sickness (defined as arthritis or arthralgia in addition to a rash or urticaria) or erythema multiforme occurred in 11 children (1.1%) who received cefaclor but in none of those who received amoxicillin. Studies suggest that serum sickness–like reactions to cefaclor are associated with lymphocyte sensitization.[168]

Carbacephems

Carbacephems have a carbon atom at position 1 of the dihydrothiazine ring (cephem nucleus), rather than a

sulfur atom. The only carbacephem currently available is loracarbef. Loracarbef is structurally similar to cefaclor but has greater chemical stability in solution. The antibacterial spectrum of loracarbef is similar to that of second-generation cephalosporins. In contrast to cefaclor, loracarbef has similar activity against penicillin-susceptible pneumococci, group A streptococci, and oxacillin-susceptible *S. aureus* and greater activity against *H. influenzae* and *M. catarrhalis*, including β-lactamase–producing strains.[94] Loracarbef is not active against *P. aeruginosa*, *Enterobacter*, *Citrobacter*, indole-positive *Proteus*, or *B. fragilis*.

Loracarbef is more stable than cefaclor to hydrolysis by lactamases but can be hydrolyzed by ESBLs. Loracarbef is available for oral administration only. It is absorbed rapidly and well; however, absorption is decreased when the agent is taken with food. Loracarbef has a longer serum half-life than some of the penicillins and can be given twice daily. It is excreted by the kidneys. Loracarbef is relatively well tolerated. Gastrointestinal complaints, including diarrhea, nausea, and vomiting, are the adverse effects most frequently reported, but they occur in fewer than 5 percent of treatment courses. The safety and efficacy of loracarbef have not been established for infants younger than 6 months of age.

Loracarbef can be used as an alternative to penicillin or erythromycin for the treatment of group A streptococcal pharyngitis.[93] The effectiveness of loracarbef is similar to that of amoxicillin and amoxicillin-clavulanate for the treatment of acute otitis media caused by susceptible bacteria.[107] Loracarbef is not effective against penicillin-nonsusceptible pneumococci; therefore, it is not considered appropriate for empirical therapy of acute otitis media.[10] For the treatment of mild-to-moderate skin and skin structure infections, the efficacy of loracarbef is comparable to that of cefaclor. Loracarbef has been approved for use in the treatment of acute bacterial sinusitis and uncomplicated urinary tract infections caused by susceptible bacteria.

Monobactams

Aztreonam is the prototype monobactam, a name that refers to the unique monocyclic nucleus. This drug has aerobic, gram-negative antibacterial activity similar to that of ceftazidime, but it has no significant gram-positive activity. Unlike most β-lactam antibiotics, aztreonam has the advantage of not inducing β-lactamase activity, and its molecular structure confers a high degree of stability to hydrolysis by β-lactamases. The mechanisms of antibiotic resistance of some gram-negative bacteria include expression of efflux pumps, reduced expression of outer-membrane porin proteins, and production of AmpC-type β-lactamases or ESBLs. Approximately 15 percent of Enterobacteriaceae in North America are resistant to aztreonam.[270] Although it is a β-lactam, aztreonam is weakly immunogenic and can be used in patients with minor forms of β-lactam allergy. Its use in pediatrics is indicated as a secondary agent for the intravenous treatment of lower respiratory tract, skin and soft tissue, urinary tract, and intra-abdominal infections caused by susceptible pathogens. Higher doses of aztreonam may be warranted for pediatric patients with cystic fibrosis. Aztreonam and aminoglycosides are synergistic in vitro against most strains of *P. aeruginosa*, many strains of Enterobacteriaceae, and other aerobic gram-negative bacilli. The safety and efficacy of aztreonam have not been established for infants younger than 9 months of age or for children with impaired renal function. However, aztreonam has been used with favorable outcomes in premature and term neonates, as well as in young infants. Updated breakpoints for enteric gram-negative organisms to aztreonam were released in 2010. The revised breakpoints include 4 or less, 8, and 16 or greater for susceptible, intermediate, and resistant organisms, respectively.[314] Aztreonam lysinate for inhalation is a novel monobactam formulation approved by the FDA in February 2010 for patients with cystic fibrosis who are colonized with *P. aeruginosa*. It has appeared to be safe and well tolerated in patients with cystic fibrosis. For children 7 years of age or older and adults, the dose recommended for inhaled aztreonam is 75 mg three times daily for 28 days.[320,250]

Carbapenems

Carbapenems differ from penicillin by virtue of the substitution of a sulfur atom by a carbon atom at position 1 of the β-lactam ring and possession of an unsaturated bond between carbon atoms at positions 2 and 3 in the structure. The carbapenem class of antimicrobial agents exhibits the broadest spectrum of activity of all β-lactam antibiotics; these agents are active against most clinically significant gram-positive and gram-negative pathogens, including anaerobic organisms. Because they are acid-labile in the stomach, they must be administered parenterally.[79] Three carbapenems, imipenem-cilastatin, meropenem, and ertapenem, are approved for use in children.

Imipenem-Cilastatin

Imipenem-cilastatin was the first carbapenem evaluated for the treatment of severe bacterial infections in children. Extensive hydrolysis of imipenem by dehydropeptidase I occurs in the proximal renal tubule and results in the production of a potentially nephrotoxic inactive metabolite. Consequently, imipenem must be administered with cilastatin, an inhibitor of dehydropeptidase I. Despite favorable in vitro efficacy against a broad spectrum of bacterial pathogens, the clinical suitability of this antibiotic is limited because of the drug's epileptogenic potential, especially in children with bacterial meningitis. Imipenem causes seizures presumably by acting as a competitive inhibitor of γ-aminobutyric acid, an inhibitory neurotransmitter.[79] Of concern is that imipenem acts as a strong inducer of production of ESBL and may select for β-lactam resistance.[84] Imipenem-cilastatin is indicated for children with severe non-CNS infections caused by susceptible organisms. The dose must be reduced for children with impaired renal function. With the advent of meropenem, imipenem-cilastatin has been used less frequently in pediatrics.

Meropenem

Meropenem was approved for use in children in 1996. It is structurally related to imipenem. However, it is more stable against degradation by renal dehydropeptidase I and therefore does not require coadministration with cilastatin. On the basis of its superior safety and efficacy, meropenem generally is considered the preferred carbapenem for treatment of childhood infections.

Mechanisms of Action. As with other β-lactam antibiotics, meropenem is bactericidal against susceptible bacteria because it inhibits bacterial cell wall synthesis. The *trans* configuration of the hydroxyethyl side chain and hydrogen atoms protect the parent β-lactam structure from inactivation by the most common β-lactamases, including almost all Bush groups 1 and 2 (Ambler classes A, C, and D) β-lactamase–producing organisms, including those that produce ESBLs (*Citrobacter*, *Enterobacter*, *E. coli*, *Klebsiella* spp., and *P. mirabilis*) or AmpC β-lactamases (*Citrobacter*, *Enterobacter*, *Pseudomonas*, and *Serratia*). In addition, the pyrrolidine side chain enhances the compound's antipseudomonal activity.[84]

Mechanisms of Resistance. Resistance may be intrinsic or acquired and is mediated by numerous mechanisms: (1) some strains of *P. aeruginosa* are deficient in the cell wall porin proteins (OprD) that usually facilitate intracellular penetration; (2) efflux pumps in some gram-negative bacteria are capable of excreting carbapenems; (3) *S. maltophilia* and some other gram-negative pathogens possess uncommon metallo-β-lactamases, the so-called carbapenemases (i.e., Bush groups 3a and 3b and Ambler class B), which form a diverse group of β-lactamases comprising the IMP and VIM families, and SPM1 and GIM1 enzymes; these carbapenemases have the ESBL and AmpC antibiotic substrate profile; (4) some gram-negative bacteria possess clavulanic acid–inhibited carbapenemases consisting of the *K. pneumoniae* carbapenemases (KPCs) (i.e., Bush group 2f and Ambler class A) or OXA enzymes (i.e., Bush group 2d and Ambler class D); and (5) MRSA strains and *E. faecium* have altered PBPs, which account for their inherent resistance. Furthermore, meropenem acts as a weak inducer of ESBLs.[46,84] At present, the risk that a single-step spontaneous mutation causes resistance among *Pseudomonas* spp. appears to be low.

In Vitro Activity. Meropenem has equivalent or slightly less in vitro potency than imipenem against gram-positive pathogens, but it is significantly more active against gram-negative organisms. The spectrum of activity of meropenem encompasses streptococci (excluding many strains of penicillin and cefotaxime-nonsusceptible *S. pneumoniae*), oxacillin-susceptible staphylococci, ampicillin-susceptible enterococci, *L. monocytogenes*, *H. influenzae*, *N. meningitidis*, Enterobacteriaceae, most strains of *P. aeruginosa*, and anaerobes (including β-lactamase–positive strains of *B. fragilis*). Pathogens resistant to meropenem are *Stenotrophomonas*, MRSA, *E. faecium*, approximately 10 percent of *Pseudomonas* strains, and most strains of penicillin and cefotaxime-nonsusceptible *S. pneumoniae*.[46,55,311] In vitro tests indicate that meropenem acts synergistically with aminoglycoside antibiotics against some isolates of *P. aeruginosa*.[147]

Pharmacokinetics. Meropenem exhibits nearly linear pharmacokinetics; increases in dosage result in approximately proportional increases in the peak plasma concentration and area under the plasma concentration–time curve (AUC).[37] Only 2 percent of the drug is bound to plasma proteins, and the drug is distributed widely into tissues and fluids.[79] The elimination half-life declines with increasing age (premature neonates, 2.9 hours; term neonates, 2 hours; children, 1.1 hours; adults, 1 hour) and is longer than that for imipenem. Because meropenem is cleared primarily by glomerular filtration, the dosage should be reduced in children with renal dysfunction.[46] Furthermore, meropenem is cleared efficiently by hemodialysis; therefore, it should be administered after the patient undergoes this procedure. Pharmacodynamic studies indicate that a favorable bacteriologic outcome is best predicted by the duration of the dosing interval for which the meropenem plasma concentration exceeds the MIC_{90} of the target pathogen.[79] Accordingly, a dose of 20 mg/kg every 8 hours achieves optimal plasma concentrations (50 to 60 μg/mL) for systemic infections that do not involve the CNS,[40] whereas a dose of 40 mg/kg every 8 hours is recommended for patients with cystic fibrosis because of accelerated drug excretion.[139] Penetration of meropenem through inflamed meninges is approximately 8 percent of the mean plasma concentration. Consequently, a dose of 40 mg/kg every 8 hours is required to achieve mean peak CSF concentrations of 0.9 to 6.5 μg/mL and ensure effective treatment of bacterial meningitis.[79,236] An administration schedule of every 12 hours probably is appropriate for neonates because of their immature renal function.[37]

Indications for Use. The FDA has approved meropenem as monotherapy for susceptible organisms causing intra-abdominal infections and bacterial meningitis in children older than 2 months of age. Meropenem should be reserved for treatment of cephalosporin-resistant nosocomial pathogens, severe polymicrobial infections with favorable susceptibility profiles, and infections that fail to respond to other antimicrobial agents. Meropenem monotherapy has clinical and microbiologic efficacy equivalent to that of third-generation cephalosporin-based regimens for septicemia and infections of the CNS, abdominal cavity, lower respiratory tract, urinary tract, and skin.[48,236] In addition, meropenem monotherapy has been shown to be equivalent to ceftazidime and amikacin and to piperacillin-tazobactam for empirical treatment of febrile children with neutropenia.[75,243] Clinical efficacy against cephalosporin-resistant pathogens also has been demonstrated in patients with cystic fibrosis.[139] In view of increasing resistance of pneumococci to β-lactam antibiotics, it is prudent to administer vancomycin with meropenem for empirical treatment of suspected bacterial meningitis until CSF microbiologic results are available. Combination therapy with aminoglycosides should be considered for suspected or proved

P. aeruginosa infections in view of emerging resistant strains and potential antibiotic synergy. The effectiveness of meropenem for neonatal infections has been assessed in small, noncomparative studies that demonstrated a favorable clinical response in neonates in whom previous conventional therapy had failed.[147]

Adverse Effects. Data from well-designed clinical trials indicate that meropenem has clinical and laboratory adverse event profiles that are equivalent to those of comparable antibiotic regimens. In contrast to treatment with imipenem-cilastatin, no increased risk for seizures exists in children with or without meningitis who are treated with meropenem,[176] presumably because meropenem has less affinity than imipenem for the γ-aminobutyric acid receptor. Meropenem can be given intravenously as small-volume bolus injections (over a course of 3 to 5 minutes) without inducing nausea or vomiting. The most common adverse reactions include diarrhea (4%), rash (2%), and vomiting (1%).[46]

β-Lactam Antibiotics Not Approved for Use in Children

Several β-lactam antibiotics available in the United States are not approved for use in children. These agents include cefonicid, a second-generation cephalosporin; cefotetan, a cephamycin; and cefoperazone, a third-generation cephalosporin. Several extended-spectrum cephalosporins and carbapenems that have activity against MRSA are undergoing clinical investigation, and the newer generation agent (ceftaroline) was approved for the treatment of acute bacterial skin and skin structure infections and community-acquired pneumonia in adults.

Ertapenem

Ertapenem is a newer, long-acting, parenteral carbapenem that initially was approved for use in adults in 2001. An indication for children was approved in 2005. However, clinical experience with this agent in children is limited. Ertapenem is distinctive because it is administered in a single daily dose in adolescents and adults and is stable against hydrolysis by many β-lactamases, except metallo-β-lactamases produced by certain bacterial nonfermenters, particularly *Pseudomonas* and *Acinetobacter*.[205] Apart from these organisms, its antimicrobial spectrum is similar to that of meropenem. Ertapenem has restricted activity against methicillin-resistant staphylococci, penicillin-nonsusceptible pneumococci, enterococci, *Pseudomonas* spp., and *Acinetobacter* spp.[169] The agent may be administered by intravenous or intramuscular routes. It exhibits nonlinear pharmacokinetics because of its concentration-dependent protein binding. The drug is excreted renally, and dosages need to be adjusted in patients with renal insufficiency.

Ertapenem is indicated for the treatment of patients 3 months of age and older with complicated intra-abdominal infections, complicated skin and soft tissue infections, community-acquired pneumonia, complicated urinary tract infections, and acute pelvic infections. Ertapenem is not recommended for the treatment of meningitis because drug concentrations in the CSF are subtherapeutic. The recommended dose in patients 3 months to 12 years of age is 15 mg/kg given parenterally twice daily, up to a maximum of 1 g/day. In older children and adults, the recommended dose is 1 g given once daily. The recommended duration is up to 14 days for intravenous administration. The most common adverse reactions, which include diarrhea, vomiting, and pain at the site of infusion, have rates comparable to those of other parenteral broad-spectrum β-lactam antimicrobials. Seizures have been reported in patients receiving ertapenem and may occur more commonly in individuals with underlying seizure disorders, brain lesions, or renal dysfunction.

In 2007, doripenem was approved for use in adults with complicated intra-abdominal infections and complicated urinary tract infections and is currently under review for treatment of hospital-acquired pneumonia, including ventilator-associated pneumonia, and catheter-related bacteremia. Doripenem has activity against gram-positive organisms, including MSSA, penicillin-susceptible and nonsusceptible *S. pneumoniae*, and *E. faecalis*. Activity against gram-negative bacteria is similar to that of meropenem and includes ESBL-producing strains. It also has good anaerobic coverage, including *B. fragilis*.[66,242]

Mechanisms of Resistance

Bacteria can acquire resistance to an antibiotic by at least four mechanisms: (1) alteration in the antimicrobial target, (2) decreased uptake of the antibiotic by expression of efflux pumps or by reduction of cell membrane permeability that is determined by porin channels, (3) production of an enzyme that inactivates the antibiotic, and (4) production of an alternative metabolic pathway that bypasses the action of the drug.[296] With respect to β-lactam antibiotics, resistance involves alterations in PBPs, leading to decreased affinity for the β-lactam (this mechanism of resistance is observed in methicillin-resistant strains of *S. aureus* and penicillin-resistant strains of *S. pneumoniae*), decreased permeability of the bacterial cell wall, resulting in diminished amounts of β-lactam reaching the PBPs, or production of β-lactamases that hydrolyze the β-lactam ring. Hydrolysis of β-lactams is the mechanism that is most significant clinically. Gram-positive bacteria excrete their β-lactamases outside the cell wall, whereas the β-lactamases of gram-negative bacteria remain in the periplasmic space. The spectrum of β-lactamase activity involves (1) narrow-spectrum penicillinases that preferentially hydrolyze penicillins; (2) broad-spectrum β-lactamases that hydrolyze penicillins and cephalosporins equally well; (3) cephalosporinases that preferentially hydrolyze cephalosporins and are resistant to inhibition by clavulanic acid; (4) and ESBLs that hydrolyze first-, second-, and third-generation cephalosporins but are susceptible to inhibition by clavulanic acid; and (5) carbapenemases that inactivate all β-lactams, including imipenem-cilastatin.[57]

Broad-spectrum β-lactamases were initially recognized in clinical isolates in the 1980s. Currently, the spread of ESBLs among enteric gram-negative organisms

in both hospital and community settings has become an important public health problem. Rates of ESBL production have been high in Latin America, Asia and the Pacific region, Europe, and North America. For Latin America, the rates of ESBL production for *E. coli* and *K. pneumoniae* were 13.5 and 44 percent, respectively, from 2004 to 2006.[257] β-Lactamases are classified on the basis of their (1) responses to β-lactamase inhibitors, (2) spectrum of antibiotic substrates (Bush-Jacoby-Medeiros classification, groups 1 to 4), or (3) primary molecular structure (i.e., Ambler classification: serine β-lactamases, which are class A, C, or D; and metallo-β-lactamases, which are class B). Bush group 2 corresponds to Ambler classes A and D, which are encoded frequently by genes carried on plasmids and easily spread among different species, whereas Bush groups 1 and 3 (Ambler classes C and B, respectively) are frequently encoded by chromosomal genes and therefore confined to certain species.[84,241] Chromosomally mediated, inducible Bush group 1 β-lactamases that are produced by certain species of *Citrobacter*, *Enterobacter*, *Morganella*, *Pseudomonas*, and *Serratia* are not inhibited by the β-lactamase inhibitors, and, consequently, they remain resistant to the accompanying β-lactam. However, *Bacteroides*, *Klebsiella*, *Legionella*, and *Moraxella* spp. produce chromosomally mediated β-lactamases that are effectively inactivated. Clavulanic acid and tazobactam are more potent inhibitors of β-lactamases. Furthermore, clavulanate induces Bush group 1 enzymes. Disks containing β-lactamase inhibitors can be used in the clinical microbiology laboratory to detect pathogens that produce Ambler class A ESBLs of the TEM and SHV types that may be overlooked otherwise.[58]

The ESBLs are classified in the Ambler class A and the functional (Bush group) 2be. ESBLs are present in various members of the Enterobacteriaceae family, particularly *E. coli* and *K. pneumoniae*, but they are also found in nonfermentative gram-negative bacteria, including *P. aeruginosa* and *A. baumannii*. Traditionally, β-lactamases derived mainly from the type A (Ambler) or 2be (Bush) groups, most commonly TEM (1 and 2) and SHV (1), derived by point mutations of the parent enzymes. These β-lactamases degrade penicillin, ampicillin, antipseudomonal penicillins, and narrow-spectrum cephalosporins (i.e., cefazolin, cephalothin, cefamandole, and cefuroxime). They are inhibited by clavulanic acid, and this allows for laboratory detection of these enzymes. Another type of class A ESBL is the expanded-spectrum CTXM, which is becoming more prevalent, particularly in *E. coli* and *K. pneumoniae*. It preferably hydrolyzes cefotaxime in contrast to ceftazidime and degrades aztreonam and the same products hydrolyzed by TEM and SHV; for some enzymes cefepime may be a substrate. More than 50 enzymes on the CTXM group have been identified and they can be divided into five groups on the basis of amino acid changes (i.e., CTXM1, CTXM2, CTXM8, CTXM9, and CTXM25). This enzyme has been disseminated on plasmids and it also inhibited by clavulanic acid. Carbapenemase of the type KPC (*Klebsiella pneumoniae* carbapenemases 1, 2, and 3) are also included on the Ambler class A β-lactamases and they have the same substrates hydrolyzed by CTXM as well as cephamycins and carbapenems. They are inhibited by amoxicillin-clavulanate. Ambler class B (Bush group 3) requires divalent cations, particularly Zn^{2+}, at the active site. These enzymes can be chromosomally encoded or transferred by plasmids. This group includes the IMP and VIM families, as well as GIM1 and SPM1 β-lactamase. These β-lactamases are included in the group of carbapenemases and degrade the same products hydrolyzed KPC. They are not inhibited by clavulanic acid. Ambler class C (Bush group 1) β-lactamases are encoded by chromosomes. They are referred as AmpC and degrade substrates of the TEM and SHV, oxyimino-cephalosporins (i.e., cefotaxime, cefpodoxime, ceftazidime, and ceftriaxone), monobactams, and cephamycins (i.e., cefotetan and cefoxitin). These enzymes are not inhibited by clavulanic acid. The OXA family β-lactamase (Ambler class D) has higher rates of hydrolysis for oxacillin in contrast to penicillin and also degrades substrates of CTXM. These enzymes are resistant to β-lactamase inhibitors. Plasmid-encoded OXA enzymes have been found in *P. aeruginosa*.[98,152,257]

Laboratory detection of ESBL includes phenotypic and genotypic tests. Phenotypic tests include screening tests by testing for resistance to cefpodoxime (hydrolyzed by all TEM, SHV, and CTXM ESBLs), cefotaxime, ceftazidime, ceftriaxone, and aztreonam. Then a confirmatory step is performed by demonstrating synergy between these agents and clavulanic acid (double-disc synergy test, combination disc method, or ESBL E tests). Genotypic tests consist of polymerase chain reaction amplification of specific genes.[98]

Treatment of ESBL-producing organisms represents a challenge. In vitro sensitivity may not correlate with effective treatment in vivo. For organisms producing TEM and SHV-type ESBL cefepime and piperacillin-tazobactam may appear susceptible in vitro but may not be susceptible if the inoculum is increased to 10^5 to 10^7 organisms. In these circumstances it may be difficult to ensure good concentrations of the antibiotic at the site of the infection (above the MIC). A carbapenem remains the antibiotic of choice for treatment of ESBL-producing organisms. AmpC-producing strains are typically susceptible to carbapenems; however, diminished porin expression can make it a carbapenem-resistant strain. Bacteria expressing IMP, VIM, or OXA-type carbapenemases usually remain susceptible to aztreonam. Care should be taken in selecting the correct antibiotic because resistance to fluoroquinolones and aminoglycosides can occur.[152] Promising alternatives include the recently approved tigecycline, a novel glycylcycline antibiotic (which shows in vitro activity against ESBL-producing *E. coli* and *K. pneumoniae*).

Vancomycin

Vancomycin, first isolated from *Amycolatopsis orientalis* (formerly called *Streptomyces*, then *Nocardia*) in soil samples from Borneo, is a high-molecular-weight, complex, soluble glycopeptide.[246] Because of a lack of adequate therapy for penicillinase-producing staphylococci, vancomycin was approved expeditiously by the

FDA in 1956 before exhaustive pharmacologic and toxicologic studies had been performed. Original preparations contained fermentation by-products that caused significant toxicity. Once the penicillinase-resistant penicillins were developed, vancomycin no longer was indispensable until the emergence of methicillin-resistant staphylococci in the late 1970s.

Mechanisms of Action

Vancomycin is slowly bactericidal against most susceptible gram-positive bacteria, except enterococci, for which it is bacteriostatic. It forms complexes with the D-alanyl-D-alanine portion of peptide precursor units and thus prevents polymerization of the phosphodisaccharide pentapeptide lipid complex and cross linking of peptidoglycan during the second stage of cell wall synthesis. Because the site of action of vancomycin is distinct from that of β-lactam antibiotics, no cross resistance among the drugs and no competitive inhibition exist. Like penicillin, vancomycin exerts its antimicrobial effect on bacteria in the active growth phase. Additionally, vancomycin alters cytoplasmic membrane permeability and impairs RNA synthesis. Animal infection models suggest that the drug exhibits time-dependent bactericidal activity against susceptible organisms, as well as a moderately long in vitro postantibiotic effect. The most important pharmacokinetic and pharmacodynamic parameter that correlates with antimicrobial efficacy is the ratio of the 24-hour AUC to the MIC (24-hour AUC/MIC).[80] A lag phase before the onset of rapid killing has been demonstrated in serum killing studies.[3]

Mechanisms of Resistance

Resistance can be categorized into three types: tolerance, acquired resistance, and inherent resistance. Some susceptible gram-positive bacteria, especially enterococci, are tolerant to the bactericidal activity of vancomycin; that is, vancomycin inhibits but does not kill the bacteria (MBC/MIC ratio >32). Staphylococci tolerant to vancomycin can have autolysin deficiencies. Although most resistance to vancomycin by gram-positive bacteria is acquired, three genera of gram-positive organisms are inherently resistant to vancomycin: *Erysipelothrix*, *Leuconostoc*, and *Pediococcus*. Five genes code for acquired vancomycin resistance in enterococci: *VanA*, *VanB*, *VanC*, *VanD*, and *VanE*.[220] The *VanA* gene that encodes the VanA phenotype (vancomycin MIC >256 and teicoplanin resistance) is on a plasmid that is easily transferable by conjugation to other enterococci. The VanB phenotype also is transferable and encodes vancomycin but not teicoplanin resistance. The presence of an inducer such as vancomycin or teicoplanin, another glycopeptide that has not been approved for use in the United States, activates the transcription of genes that encode ligases necessary for resistance to vancomycin. Some enzymes make cell wall precursors ending in D-alanyl-D-lactate located at the end of the pentapeptide side chain, to which vancomycin binds with very low affinity. Other enzymes inhibit or alter the synthesis of endogenous cell wall precursors ending in D-alanyl-D-alanine, to which vancomycin is unable to bind. The finding that vancomycin resistance genes can be transferred experimentally from vancomycin-resistant enterococci (VRE) to staphylococci highlights the potential risk for spread of resistance by means of naturally occurring plasmid or transposon-mediated conjugative systems.[220] Although vancomycin resistance can affect susceptibility to other investigational glycopeptides, no cross resistance exists between vancomycin and other unrelated antibiotics. Resistance to vancomycin rarely develops during appropriate therapy, perhaps because of its multiple mechanisms of action, but prolonged or indiscriminate use of the drug can contribute to selective pressure and result in the development of vancomycin-resistant enterococci colonizing the gut. Of great concern is the emergence of invasive strains of multidrug-resistant enterococci (≤14% of health care–associated enterococcal strains)[199] and staphylococci, for which only a few therapeutic options exist, including linezolid and other antimicrobials not approved for use in children such as quinupristin-dalfopristin, daptomycin, and tigecycline (a novel glycylcycline antibiotic). *VanC* genes are expressed constitutively in *Enterococcus gallinarum*, conferring low-level vancomycin resistance. This organism remains susceptible to β-lactams (ampicillin). The first strains of *S. aureus* with intermediate resistance to vancomycin/glycopeptide (VISA/GISA) were detected in the United States in 1997. Soon thereafter, three cases of vancomycin-resistant *S. aureus* were isolated. The mechanism for this high-level vancomycin resistance involves the horizontal transfer of a transposon containing *VanA* and associated genes from vancomycin-resistant enterococci.[259] Glycopeptide-resistant isolates were found to have thicker extracellular matrices, a characteristic that may cause vancomycin to become trapped in the outer layers of the cell wall and may limit access to the cytoplasmic membrane where the functional targets are located. Pneumococci tolerant to vancomycin were described first in 1999.[235] These strains escape lysis and killing by vancomycin because of an alteration in the regulation of autolysin. Their prevalence is 4 to 10 percent of nasopharyngeal and invasive isolates, and they are associated with increased mortality when etiologic in meningitis.[266] In 2006, the CLSI modified the MIC breakpoints for *S. aureus* to vancomycin: from 4 μg/mL or less to 2 μg/mL or less for "susceptible," from 816 μg/mL to 48 μg/mL for "intermediate," and from 32 μg/mL or greater to 16 μg/mL or greater for "resistant." This change was made to increase the detection of heterogeneously resistant isolates and based on clinical data showing less response to vancomycin when the MIC is 4 μg/mL or greater.[297] The CDC recommends that the use of vancomycin be restricted appropriately to reduce the risk for inducing vancomycin resistance.[63]

In Vitro Activity

The in vitro spectrum of activity for vancomycin is limited to gram-positive aerobic and anaerobic bacteria, with little, if any, activity against aerobic or anaerobic gram-negative bacilli, except *Chryseobacterium meningosepticum.* Group A streptococci, pneumococci, *Corynebacterium*

spp., and *C. difficile* are highly susceptible to vancomycin, whereas *L. monocytogenes*, microaerophilic and anaerobic streptococci, enterococci, coagulase-positive and coagulase-negative staphylococci, Bacillus anthracis and other spp., *Lactobacillus*, *Actinomyces*, and other *Clostridium* spp. have higher MIC values that are still in the susceptible range. Pathogens resistant to vancomycin include *Erysipelothrix* and *Leuconostoc* and *Pediococcus* spp., which can cause serious infections in immunocompromised patients. The bactericidal activity of vancomycin combined with gentamicin has been shown to be synergistic in vitro against strains of enterococci (provided there is no high-level gentamicin resistance; MIC >2000 μg/mL), nonenterococcal group D streptococci, viridans streptococci, and most methicillin-susceptible *S. aureus* and MRSA. Addition of rifampin, gentamicin, or both, results in improved cure rates for *S. epidermidis* prosthetic valve endocarditis.[199] Although vancomycin has activity against many gram-positive bacteria, it is not the most active agent for these organisms, but it is the drug of choice for multidrug-resistant bacteria such as methicillin-resistant staphylococci and highly penicillin-resistant and cephalosporin-resistant pneumococci.

Pharmacokinetics

Intravenous administration of vancomycin is preferred because intramuscular injection causes pain and tissue necrosis. Intravenous preparations must be diluted further in normal saline or dextrose solutions before beginning slow infusion. Vancomycin is approximately 55 percent bound to serum proteins and diffuses well into most body tissues, with adequate concentrations achieved in pericardial, pleural, ascitic, bone, and synovial fluids, but not in aqueous humor or bile. Vancomycin does not diffuse well into CSF in the absence of inflamed meninges, but CSF concentrations of 7 to 21 percent of concomitant serum levels can be achieved during therapy for meningitis when higher doses (15 mg/kg every 6 hours) are administered. The bone-to-serum ratio of vancomycin is 10 percent, but this figure increases up to 30 percent in infected bone. Vancomycin remains active at pH 6.5 to 8, and concentrations achieved in abscess fluid approximate serum levels.[199] Intrathecal or intraventricular administration has been used infrequently for CNS infections that are difficult to eradicate.[198] Vancomycin is not metabolized significantly and is excreted by glomerular filtration. The mean serum elimination half-life in adults with normal renal function is 6 hours. For children, it ranges from 5 to 10 hours in newborns and 4 hours in older infants to 2 to 3 hours in children. In anephric patients, the elimination half-life extends to 7 or more days. Hemodialysis removes small amounts of vancomycin, whereas peritoneal dialysis may reduce serum concentrations by approximately 40 percent. Nomograms and patient-individualized bayesian dosing regimens have been used for vancomycin dosing in renal failure in adults.[182,214]

Current recommendations for vancomycin monitoring in adult patients include checking trough concentrations rather than peak values as the most accurate method for vigilance of efficacy and toxicity. Trough values should be checked before the fourth dose of the antibiotic (steady state). Minimal concentration should be maintained above 10 mg/L, and target concentrations of 15 to 20 mg/mL are preferred for complicated infections secondary to *S. aureus* (bacteremia, endocarditis, osteomyelitis, meningitis, and hospital-acquired pneumonia).[268]

Indications for Use

Because of the potential for development of resistance, vancomycin should be reserved for patients with moderate-to-severe infections caused by vancomycin-susceptible bacteria that are resistant to other antibiotics. Vancomycin can be used for the treatment of infections caused by β-lactam–susceptible and vancomycin-susceptible bacteria in patients with hypersensitivity reactions to β-lactam antimicrobial agents. Empirical therapy for patients with ventricular shunt–related and catheter-associated infections frequently includes vancomycin to provide activity against coagulase-negative staphylococci. Vancomycin can be used in combination with gentamicin, rifampin, or both, for bactericidal synergistic activity to treat documented prosthetic device–related *S. epidermidis* infections, methicillin-resistant staphylococcal endocarditis, or endocarditis caused by high-level penicillin-resistant, aminoglycoside-susceptible strains of enterococci. *S. epidermidis* infections of long-term intravenous catheters usually can be cured without removal of the device.[199] In addition, vancomycin is the drug of choice in patients with immediate-type hypersensitivity to penicillins and other β-lactam antibiotics for prophylaxis (e.g., in gastrointestinal or genitourinary procedures) or treatment of endocarditis caused by streptococci, enterococci, and staphylococci.[20,83] Empirical treatment of bacterial meningitis suspected or proved to be caused by *S. pneumoniae* in children 1 month of age or older should consist of vancomycin in addition to a third-generation cephalosporin until susceptibility data are available; if cephalosporin resistance is documented, rifampin should be added to the regimen. However, vancomycin need not be used if compelling evidence implicates pathogens other than *S. pneumoniae*, such as the observation of gram-negative diplococci on a CSF smear. Vancomycin also is indicated for the treatment of infections with penicillin-resistant streptococci, *C. jeikeium*, and *Bacillus* spp., penicillin-resistant enterococci, as well as for bacteremia, pneumonia, cellulitis, and osteomyelitis caused by methicillin-resistant staphylococci. Some experts advocate the addition of nafcillin, oxacillin, gentamicin, or rifampin for optimal coverage of oxacillin-susceptible *S. aureus* in severely ill patients who are receiving empirical treatment with vancomycin because certain strains of staphylococci are tolerant to vancomycin.[123] Proof of enhanced efficacy with combination therapy in this setting is lacking. Although nonabsorbable oral vancomycin is effective therapy for *C. difficile* colitis, oral metronidazole represents first-line therapy; vancomycin should be given only for metronidazole treatment failures, to limit the development of vancomycin-resistant enterococci. Vancomycin is among

the agents of choice for the treatment of meningitis caused by *C. meningosepticum*.

Adverse Effects

The purification of vancomycin allegedly decreased the frequency of adverse reactions noted several decades ago. The most common adverse effect is "red man" or "red neck" syndrome or glycopeptide-induced anaphylactoid reaction manifested as flushing of the face and upper part of the trunk, pruritus during vancomycin infusion, angioedema, and, rarely, hypotension. Vancomycin directly causes release of histamine from mast cells by non–immune-mediated mechanisms. Because it is a dose- and rate-dependent reaction, administering doses less than 500 mg, prolonging the infusion period to at least 1 hour, or both, decreases the risk for occurrence. Pretreatment with histamine-1–receptor antagonists (i.e., diphenhydramine or hydroxyzine) prevents the development of this reaction, and symptoms usually resolve promptly after discontinuation of the infusion.

Controversy surrounds the issue of vancomycin-induced ototoxicity and nephrotoxicity.[54] Such toxicity has not been demonstrated in experimental animal models. Although numerous cases of toxicity in humans have been reported, the literature is difficult to interpret because of confounding variables, including recent or concurrent use of aminoglycosides or other ototoxic or nephrotoxic agents, lack of identification of antecedent otologic or renal disease, and inconsistencies in sampling methods when measuring serum vancomycin concentrations. Tinnitus and high-tone hearing loss have been associated with the administration of vancomycin, particularly when the peak serum levels exceed 50 µg/mL. If vancomycin is ototoxic, whether toxic peak or toxic trough serum concentrations are responsible is not clear. Several studies suggest an increased risk for nephrotoxicity when aminoglycosides are used concurrently with vancomycin, especially when they are administered for longer than 21 days.[120] Other adverse effects seen occasionally with the use of vancomycin include reversible neutropenia, thrombocytopenia, drug fever, and macular rash.

The usefulness of serum vancomycin concentration determinations is controversial because a definitive relationship between vancomycin concentration and either adverse effects or clinical outcome has not been proved.[59,61,213] Until the significance of vancomycin serum concentration determinations has been clarified, monitoring has been suggested for the following clinical situations only: (1) patients with altered renal function, including premature infants; (2) patients receiving larger than normal dosages, especially those with meningitis in whom adequate CSF values are necessary; (3) anephric patients undergoing hemodialysis (to avoid subtherapeutic vancomycin concentrations during prolonged dosing intervals); and (4) patients receiving concomitant therapy with nephrotoxic agents.[213] Because serum vancomycin values commonly are subtherapeutic in the first days of treatment for severe sepsis, presumably because of larger volumes of distribution of vancomycin in these ill children, we recommend an initial dosage of 60 mg/kg/day in four divided doses.

Daptomycin

Daptomycin is a cyclic lipopeptide derived from the fermentation of *Streptomyces roseosporus*. It has been approved for treatment of adults with complicated skin and soft tissue infections, endocarditis, and sepsis. It is a parenteral lipopeptide that disrupts cell membrane potential, and, unlike vancomycin, it is rapidly bactericidal against MRSA strains. Daptomycin's mechanism of action involves a calcium-dependent insertion into the bacterial cell membrane resulting in rapid depolarization with resulting cell death, without cell lysis, in a concentration-dependent activity. It is administered once daily. Pediatric experience is limited, with few case reports and case series published in children. A retrospective review of 16 pediatric cases with invasive gram-positive bacterial infections (MRSA, $n = 14$; MSSA, $n = 1$; and vancomycin-resistant *Enterococcus* [VRE], $n = 1$) showed clinical improvement after the addition of daptomycin to conventional therapy in patients with persistent bacteremia and severe clinical disease.[11] A pharmacokinetic analysis evaluated single-dose daptomycin for children 2 to 6 years of age. A dose of 8 to 10 mg/kg was shown to be well tolerated and reached appropriate systemic exposure, comparable to that in adults receiving doses of 4 to 6 mg/kg.[1] Daptomycin is active against *S. aureus* (including MRSA, MSSA, and GRSA), streptococci, and *Enterococcus* spp. This antibiotic is not effective in cases of pneumonia because it is inactivated by surfactant. Side effects of daptomycin include prolongation of prothrombin time and myopathy, with elevation of the serum creatinine kinase, which should be monitored weekly during treatment.

Telavancin

Other semisynthetic glycopeptides approved for adults include telavancin and dalbavancin. They may have some advantage over vancomycin and daptomycin in that resistance of MRSA is less likely because of their dual mechanisms of action. Telavancin was approved by the FDA in 2009 for treatment of complicated skin and skin structure infections caused by susceptible gram-positive bacteria in adults. It is a lipoglycopeptide that contains a hydrophobic side chain linked to the vancosamine sugar and a hydrophilic group on the 4 position of amino acid 7. The hydrophobic chain provides improved binding activity for D-alanine-D-alanine–containing peptidoglycan intermediates. Its dual mechanism of action includes binding the peptidoglycan precursor at the D-alanine-D-alanine terminus with subsequent inhibition of transglycosylation (peptidoglycan polymerization) and then inhibition of transpeptidation. The second mode of action includes binding to the cell membrane and triggering rapid concentration-dependent dissipation of cell membrane potential with leakage of cytoplasmic adenosine triphosphate (ATP) and potassium loss. Telavancin is active

against MSSA, MRSA, GISA, hGISA, coagulase-negative staphylococci, streptococci (including group A and group B β-hemolytic streptococci and *S. pneumoniae*), *Clostridium* spp., and *Actinomyces israelii*. It does not have activity against VRE (both VanA and VanB). It has high level of protein binding (~93%) and small volume of distribution. It is not inactivated by surfactant. Telavancin is mainly eliminated by renal excretion.[275]

COLISTIN (COLISTIMETHATE SODIUM: POLYMYXIN E)

Colistin is a cationic, cyclic polypeptide antibiotic that is structurally and pharmacologically related to polymyxin B. Colistin is less active in vitro and less toxic than is polymyxin B. Colistin was discovered in 1949 and is obtained from cultures of *Bacillus polymyxa* subsp. *colistinus*. The polymyxins have been used extensively for decades in topical ophthalmic and otic solutions. However, because of reports of common and serious nephrotoxicity and neurotoxicity, parenteral use of these drugs was abandoned in the early 1980s, except for treatment of multidrug-resistant, gram-negative bacterial infections in children and adults with cystic fibrosis. The emergence of gram-negative bacteria resistant to most classes of antibiotics and the lack of effective new antimicrobial agents led to the reconsideration of colistin as a valuable therapeutic option. Studies of patients who received intravenous polymyxins for the treatment of serious multidrug-resistant *P. aeruginosa* and *A. baumannii* infections, including pneumonia, bacteremia, and urinary tract infections, led to the conclusion that these antibiotics have acceptable effectiveness and considerably less toxicity than was reported previously.[167]

Mechanisms of Action

Colistimethate sodium is inactive until it is hydrolyzed to sulfomethylated derivatives and colistin, which acts as a cationic detergent with both lipophilic and lipophobic components. It damages the cytoplasmic membrane by displacing calcium and magnesium and binding to anionic lipopolysaccharide molecules and leads to permeability changes in the cell membrane, leakage of osmotically active intracellular metabolites and nucleosides, and cell death. Furthermore, colistin binds and neutralizes the lipid A portion of lipopolysaccharide in vitro; however, the clinical implications of this antiendotoxin activity are unknown.[99]

Mechanisms of Resistance

Gram-negative bacteria can develop resistance to colistin by means of inherited or acquired mechanisms. Inherited mutations occur infrequently and are not influenced by exposure to colistin. Acquired resistance rarely may be induced by prolonged exposure to the drug. Studies of polymyxin-resistant *P. aeruginosa* suggest that the development of resistance arises from modifications of the cell membrane, such as reductions in lipopolysaccharide, certain proteins or lipids, or magnesium or calcium. Currently, no evidence of efflux pump or enzyme-mediated resistance exists. Complete cross resistance occurs between colistin and polymyxin B, but not other antimicrobial agents.

In Vitro Activity

Colistin is highly active against many strains of aerobic gram-negative bacteria, including *Acinetobacter*, *Citrobacter*, *E. coli*, *Enterobacter*, *H. influenzae*, *Klebsiella*, *Morganella morganii*, *P. aeruginosa*, *Salmonella*, *Shigella*, and variable numbers of *Stenotrophomonas* strains. However, the antibiotic is inactive against most strains of *Brucella*, *Burkholderia cepacia*, *Edwardsiella*, *Proteus*, *Providencia*, *Serratia*, gram-negative cocci, gram-positive bacteria, and anaerobic bacteria. The CLSI defined bacterial resistance to colistin as an MIC of 4 μg/mL or greater. However, the sulfate form of colistin, which usually is used for in vitro testing, often is fourfold to eightfold more active than the sulfomethyl form, which is used in the parenteral formulation. Limited in vitro and clinical data suggest that synergism exists with colistin and other antimicrobial agents such as aminoglycosides, antipseudomonal β-lactams, fluoroquinolones, rifampin, and TMP-SMX.[99,167]

Pharmacokinetics

The pharmacologic evaluation of the polymyxins was performed decades ago. Consequently, pharmacokinetic and pharmacodynamic information is limited. Colistin is not absorbed from the gastrointestinal tract and must be given parenterally. The drug is distributed widely in the body, except for bones and synovial, pleural, and pericardial fluids. In a reported case of multidrug-resistant *A. baumannii* meningitis in an adolescent, parenterally administered colistin achieved a concentration in the CSF that was 25 percent of the serum concentration, and it cured the infection.[155] More than 50 percent of the agent binds to serum proteins. Colistimethate sodium and its metabolites are excreted mainly by the kidneys through glomerular filtration. Therefore, the dosage and frequency of administration should be decreased in children with renal impairment. Colistin is rapidly bactericidal against susceptible bacteria in a concentration-dependent manner, and it has a postantibiotic effect.[99,167] Considering these pharmacologic parameters, there may be a theoretical benefit in administering colistin less frequently with higher doses, but no clinical data validate this hypothesis.

Indications for Use

Colistin has been administered intravenously to infants and children of all ages for the treatment of acute or chronic infections caused by susceptible gram-negative organisms, particularly multidrug-resistant strains of *Pseudomonas* and *Acinetobacter* in patients with cystic fibrosis or complicated health care–associated infections. Colistin should be reserved for use when other more

effective and less toxic antimicrobial agents are contraindicated or ineffective. The dosage of colistimethate sodium is expressed in terms of colistin. The usual parenteral dosage for adults and children with normal renal function is 2.5 to 5 mg/kg (75,000 to 150,000 IU/kg)/day divided into two to four doses, depending on the severity of infection (maximum, 300 mg/day). Intramuscular administration is not recommended because it causes severe pain at the injection site. Experience with the use of colistimethate sodium administered by nebulization for multidrug-resistant, gram-negative respiratory infections in patients with cystic fibrosis is extensive. Successful use of colistimethate sodium by the intraventricular route also has been reported. Colistin sulfate in combination with neomycin sulfate and hydrocortisone acetate is available in the United States for otic use. Colistin sulfate for oral administration no longer is available in the United States. Polymyxin B sulfate is available for topical use.[99]

Adverse Effects

Nephrotoxicity and neurotoxicity are the most serious adverse effects and occur most frequently when the drug is administered in higher than recommended doses, in patients with renal insufficiency, or in combination with other nephrotoxic agents. Progressive azotemia or acute tubular necrosis may occur, but renal dysfunction usually is reversible when the antibiotic is discontinued. Renal function should be monitored closely during therapy, and colistin should be discontinued immediately if urine output diminishes or concentrations of blood urea nitrogen or creatinine increase. Transient effects on the nervous system, including dizziness, weakness, paresthesia, numbness, vertigo, ataxia, blurred vision, and slurred speech may occur, but these symptoms are reversible and may be alleviated by reducing the dosage of colistin. Coma, psychosis, seizures, and noncompetitive neuromuscular blockade causing apnea also have been reported and warrant prompt discontinuation of the drug.

AGENTS THAT TARGET PROTEIN SYNTHESIS

Aminoglycosides

Aminoglycosides are natural and semisynthetic compounds that consist of at least two amino sugars bound by a glycosidic linkage to a hexose nucleus, the aminocyclitol ring. A more appropriate name would be aminoglycosidic aminocyclitols. Streptomycin, isolated from *Streptomyces griseus*, was the first aminoglycoside and was available for use in 1944. Many aminoglycosides have been isolated or developed since that time. The suffix denotes the origin of the aminoglycoside—those ending with the suffix *mycin* were derived from *Streptomyces* spp., whereas those ending with *micin* were derived from *Micromonospora* spp. Currently, eight aminoglycosides are approved for use in the United States (Table 235-7), and several more are available in other countries. Despite the development of less toxic antibiotics with broad-spectrum activity, aminoglycosides continue to fulfill an essential role in the treatment of severe infections caused by aerobic gram-negative bacilli and enterococci.

TABLE 235-7 **Classification Scheme for Aminoglycosides**

Aminocyclitol Ring	Family	Member
Streptidine	Streptomycin	Streptomycin
2-Deoxystreptamine	Kanamycin	Kanamycin Amikacin Tobramycin
2-Deoxystreptamine	Gentamicin	Gentamicin Netilmicin
2-Deoxystreptamine	Neomycin	Neomycin Paromomycin

Mechanisms of Action

Against susceptible bacteria, aminoglycosides demonstrate rapid, concentration-dependent bactericidal activity.[97,310] They exert their effect by binding irreversibly to the 30S subunit of the bacterial ribosome, which results in inhibition of protein synthesis and induction of translational errors. Bacterial uptake of aminoglycosides can be facilitated by concomitant therapy with cell wall–active antibiotics such as β-lactams or vancomycin. Penetration of the outer membrane of gram-negative bacteria is mediated by a self-promoted uptake process involving aminoglycoside-induced disruption of magnesium bridges between adjacent lipopolysaccharide molecules. Passage through porin channels is unlikely because of the large size of aminoglycosides. Subsequent transport into cytoplasm and attachment to the 30S ribosomal subunit require two energy and oxygen-dependent steps, energy-dependent phases I and II (EDPI and EDPII), that use an electrochemical proton gradient. EDPI is inhibited by hyperosmolarity, low pH, and anaerobic conditions. Unlike other protein synthesis inhibitors, which usually are bacteriostatic, aminoglycosides are bactericidal. Binding of aminoglycosides to the 30S subunit does not prevent formation of the initiation complex of peptide synthesis. However, it disrupts elongation of the peptide chain by impairing the proofreading process, an impairment that results in translational inaccuracy. Aberrant protein products may be inserted in the cell membrane and cause altered permeability. The primed amino sugar and 2-deoxystreptamine groups are essential for the ribosome-specific activity of aminoglycosides.[211]

Mechanisms of Resistance

The prevalence of acquired aminoglycoside resistance is relatively low, and its development during therapy is an unusual event. Bacteria can acquire resistance to aminoglycosides because of alterations in the bacterial target, reduced bacterial cell permeability or uptake, or modification of the antibiotic by bacterial enzymes, the last being most significant clinically.[86] Mutations in the

aminoglycoside-binding site of the 30S ribosome have been associated with high-level resistance to streptomycin but not to other aminoglycosides, possibly because, unlike in streptomycin, they bind to multiple sites on the ribosome. Facultative aerobic bacteria causing infection in sites with reduced oxygen tension, anaerobic bacteria, and such fermentative bacteria as streptococci are inherently resistant to aminoglycosides because they are unable to generate an electrochemical proton gradient sufficient for aminoglycoside transport into the cytoplasm. Other bacteria can acquire resistance because of reduced permeability or lack of transport, as demonstrated in staphylococci, in which resistance to aminoglycosides quickly develops when monotherapy is administered. *P. aeruginosa*, other nonfermenting gram-negative bacilli, and, less frequently, members of the Enterobacteriaceae can acquire a moderate level of resistance to all aminoglycosides as a result of various mechanisms that interfere with uptake, cytoplasmic transport, or regulation of the anaerobic respiratory pathway. Plasmid-mediated production of aminoglycoside-modifying enzymes is the most common mechanism of acquired resistance. Many enzymes have different substrate specificities, several of which can be elaborated simultaneously in the same bacterium. These acetyltransferases, nucleotidyltransferases, and phosphotransferases interact with amino or hydroxyl groups on the aminoglycoside and modify the aminoglycoside so that it binds poorly to the 30S ribosome, thereby usually resulting in high-level resistance.[211] Gentamicin and tobramycin are each susceptible to at least five modifying enzymes, whereas amikacin possesses an aminohydroxybutyryl group that prevents enzymatic modification at multiple sites. Consequently, more than 80 percent of gentamicin-resistant strains of Enterobacteriaceae and 25 to 85 percent of gentamicin-resistant *P. aeruginosa* strains are susceptible to amikacin.[178]

In Vitro Activity

The in vitro antibacterial spectrum of aminoglycosides includes a wide range of aerobic gram-negative bacilli, many oxacillin-susceptible staphylococci, many enterococci, and some mycobacteria.[212] Some gram-negative bacilli, including *B. cepacia* and *S. maltophilia*, are consistently resistant to all aminoglycosides. The spectra of activity of gentamicin, tobramycin, and netilmicin are similar, and strains resistant to one usually are resistant to the others. The major advantage of tobramycin currently is its activity against some strains of *Acinetobacter* and indole-positive Proteae (*Morganella* spp., *Proteus* spp., *Providencia* spp.) that are resistant to gentamicin.[258] Because many aminoglycoside-modifying enzymes are active against gentamicin, tobramycin, and netilmicin but inactive against amikacin, amikacin frequently is prescribed for empirical treatment of nosocomial gram-negative bacillary infections. Amikacin also has activity against the *Mycobacterium avium* complex (MAC), some rapidly growing mycobacteria, and *Nocardia asteroides*. Netilmicin is less active than other aminoglycosides against *P. aeruginosa*, but it can have activity against some gentamicin-resistant, aerobic, gram-negative bacilli. Although gentamicin, tobramycin, amikacin, and netilmicin have similar spectra of activity, susceptibility testing is recommended because of geographic and interhospital variation in resistance patterns. Lack of activity against *P. aeruginosa*, *Klebsiella*, and *Serratia* has limited the use of kanamycin. Streptomycin is inactive against many gram-negative enteric bacilli but does have activity against *Francisella tularensis*, *Yersinia pestis*, and *Mycobacterium tuberculosis*.

Pharmacokinetics

Aminoglycosides have in common many pharmacokinetic characteristics. They are highly polar, water-soluble compounds that are positively charged cations at neutral pH. Their antibacterial activity is pH-dependent, with increased activity at higher pH. They are relatively resistant to degradation at various temperatures and pH values. After parenteral administration, aminoglycosides are distributed rapidly in extracellular body water, with slow accumulation in tissues. The volume of distribution is decreased (with respect to total body weight) in obese patients and is increased in patients with illnesses associated with edema, such as severe infections, burns, congestive heart failure, and ascites. With the exception of proximal renal tubular cells and possibly inner ear hair cells, penetration into other body compartments is impaired because of lipid insolubility, polycationic charge, and size of the aminoglycoside. Proximal renal tubular cells absorb aminoglycosides through carrier-mediated pinocytosis, and, as a result, renal cortical concentrations exceed those in plasma. Aminoglycosides do not penetrate the blood-brain barrier in the absence of meningeal inflammation, but with inflammation, approximately 20 to 25 percent of the serum concentration penetrates the CSF. These CSF concentrations are low in relation to the MIC of the meningeal pathogen for which it is given. Thus, because of this narrow therapeutic-toxic index, monotherapy for gram-negative bacillary meningitis with aminoglycosides is not recommended. Aminoglycosides are not metabolized and, after parenteral administration, are excreted unchanged in the kidney by glomerular filtration, with approximately 5 percent of excreted drug reabsorbed in the proximal tubular cells. Minimal amounts are excreted in saliva and feces. Urine concentrations exceed those in plasma by 25 to 100 times.

After intramuscular injection, aminoglycosides are absorbed completely, and peak serum concentrations are achieved within 90 minutes, except in some disease states that interfere with tissue perfusion, such as hypotension. When administered intravenously, the infusion should be given slowly over the course of 30 to 60 minutes to avoid the development of potential adverse effects. Peak serum concentrations are achieved within 30 to 60 minutes after infusion. Because of the polar nature of these drugs, absorption after oral administration is insignificant and inadequate to treat systemic infections, but aminoglycosides can accumulate in the presence of renal failure and result in concentrations sufficient to cause toxicity. Although aminoglycosides are nonirritating when they are instilled into pleural or peritoneal spaces, their absorption is rapid and can result in significant toxicity. In contrast, instillation into the lateral ventricles or

irrigation of the bladder has not been associated with significant systemic absorption. In contrast to parenteral administration, aerosol administration of aminoglycoside results in higher concentrations in bronchial secretions and less toxicity.[254] Indiscriminate use of topical aminoglycosides in the form of ointments, creams, or ophthalmic solutions may lead to the rapid development of aminoglycoside resistance, especially in immunocompromised patients.

Antimicrobial dosing in newborns and young infants differs from that in older children and adults because of developmental changes in renal function and increased total body water composition. Neonates and young infants have a larger volume of distribution and a reduced glomerular filtration rate; these differences are more pronounced in premature neonates with very low birthweight.[251] Therefore, twice-daily regimens have been the standard of care in newborn infants for years. Once-daily gentamicin dosing of 4 mg/kg in term neonates has been studied extensively and is used routinely in many nurseries; no differences in effectiveness or toxicity have been observed.[310] The aminoglycoside dosing schedule currently approved for use in older infants and children is a three-times-daily regimen. Because aminoglycosides demonstrate concentration-dependent bactericidal activity, higher peak serum concentrations result in more extensive and more rapid killing.[310] Aminoglycosides also demonstrate a postantibiotic effect against susceptible aerobic gram-negative bacilli in vitro and in vivo.[321] Furthermore, host leukocytes display enhanced phagocytosis of aminoglycoside-exposed bacteria in vitro, referred to as *postantibiotic leukocyte enhancement*.[106] The higher the peak serum concentration, the longer is the duration of the postantibiotic effect. In the presence of normal renal function, the serum concentration is low or undetectable before the administration of the next dose (trough value), but antibacterial activity persists because of the postantibiotic effect. These characteristics favor single-daily dosing. Numerous studies in adults have shown that once-daily dosing of aminoglycosides (i.e., amikacin, gentamicin, tobramycin, or netilmicin) is either equivalent or superior to multiple-daily dosing with regard to clinical and bacteriologic effectiveness, nephrotoxicity, ototoxicity, mortality, and cost-effectiveness.[310] The Hartford nomogram originally described by investigators from Hartford, Connecticut, commonly is used to guide extended-interval aminoglycoside dosing for adults. In adults, a single serum concentration of gentamicin or tobramycin is obtained 8 to 12 hours after the start of the infusion of the first dose and plotted on the nomogram to determine the appropriate dosing interval.[112] Similar nomograms for children have not been validated. Nonetheless, published guidelines support 7.5 mg/kg per dose of gentamicin for infants and children up to 10 years of age; for adolescents and adults, 6 to 7 mg/kg per dose is appropriate.[77,310] Extended-interval aminoglycoside dosing is contraindicated if the patient's volume status is altered (e.g., third spacing, thermal injury >20 percent total body surface area), optimal dosing regimen is predefined (e.g., in cystic fibrosis and endocarditis), renal function is impaired, or immune status is compromised.

Indications for Use

The major use of aminoglycosides in children (usually in combination with other antibacterial agents) is for serious infections caused by gram-negative enteric bacilli, including neonatal sepsis, sepsis in a child with malignant disease or an immunologic defect, abdominal and systemic infections associated with spillage of fecal contents into the peritoneum, endocarditis caused by certain susceptible bacteria, and complicated urinary tract infections. Because gentamicin is the least expensive aminoglycoside and the one with which physicians have the most experience, it often is considered the first-line agent for empirical treatment of suspected aerobic gram-negative bacillary infections in institutions with minimal background resistance. Combinations of an aminoglycoside and a cell wall–active antibiotic have been used for synergistic bactericidal activity. Gentamicin or streptomycin, in combination with penicillin G, ampicillin, or vancomycin, is recommended for the treatment of endocarditis caused by susceptible enterococci, viridans streptococci, or *Streptococcus bovis*. Administration of gentamicin for 3 to 5 days, in combination with an antistaphylococcal agent, should be considered for the treatment of staphylococcal endocarditis.[20] An aminoglycoside combined with an acylureidopenicillin, ceftazidime, cefepime, or a carbapenem is recommended for serious infections caused by *P. aeruginosa*. Amikacin often is used for empirical treatment of nosocomial aerobic, gram-negative, bacillary infections in patients in institutions having significant resistance to gentamicin and tobramycin. Streptomycin is indicated for use alone or in combination with other antibiotics for the treatment of tularemia and plague and in combination with other agents for the treatment of tuberculosis, brucellosis, and enterococcal endocarditis. For such purposes, gentamicin could be a more suitable agent for some of these conditions, such as brucellosis, tularemia, and plague. Paromomycin is too toxic for parenteral use, but when administered orally, it has been useful in the treatment of asymptomatic intestinal amebiasis, *Dientamoeba fragilis* infection, and *Giardia lamblia* infection during pregnancy. Tobramycin inhalation solution is approved by the FDA for twice-daily dosing in patients with cystic fibrosis.

Adverse Effects

Although aminoglycosides have intrinsic toxicity, allergic reactions are uncommon. All aminoglycosides can injure the proximal renal tubules, the cochlea, the vestibular apparatus, or a combination thereof and can cause neuromuscular blockade, but the risk varies with each agent. Because aminoglycosides do not induce a significant inflammatory response, pain at intramuscular injection sites and phlebitis at intravenous infusion sites are unusual. Hypersensitivity reactions and drug fever are rare events.

Many theories have been postulated regarding the mechanism of nephrotoxicity,[210] including inhibition of lysosomal phospholipases within the proximal renal tubules. Clinical findings include a mild, nonoliguric decrease in the glomerular filtration rate that typically is

reversible. In contrast to traditional dosing, once-daily dosing causes similar or lower rates of nephrotoxicity.[77,310] In humans, nephrotoxicity has been associated with prolonged duration of therapy at high dosages, previous aminoglycoside therapy, administration of drugs to critically ill patients with intravascular volume depletion or hyponatremia and to those with impaired kidney function, and concomitant administration of other potentially nephrotoxic agents such as amphotericin B and loop diuretics.[88]

The mechanism by which aminoglycosides cause vestibular and cochlear ototoxicity has not been elucidated fully. Cochlear damage is manifested as tinnitus or high-frequency hearing loss, whereas vestibular toxicity is associated with vertigo, nystagmus, and ataxia.[15] Damage can be unilateral or bilateral. Occasionally, the ototoxicity is reversible, but permanent damage occurs commonly. Mild cochlear damage may not be recognized because the high-frequency hearing range is affected first. Conventional audiograms that do not test high-frequency ranges may not detect cochlear injury. Delayed onset of high-frequency hearing loss has been observed in humans. Factors that increase the risk for development of aminoglycoside ototoxicity in humans include impaired renal function and prolonged duration of treatment. Although elevated serum peak and trough concentrations are thought to contribute to ototoxicity, a specific threshold for peak or trough concentrations has not been established. Neuromuscular blockade can occur after rapid intravenous infusion, after extensive peritoneal irrigation, or during routine parenteral aminoglycoside administration in patients with underlying conditions that affect the neuromuscular junction, such as myasthenia gravis and botulism, or during concomitant administration of agents that act on the neuromuscular junction, such as succinylcholine. Hypomagnesemia in the neonate may predispose to hearing loss.

To avoid toxicity and ensure therapeutic values, concentrations of aminoglycosides in serum should be monitored in all patients who have impaired renal function or who receive other nephrotoxic medications or prolonged treatment; such monitoring is particularly relevant to preterm, low-birth-weight infants. Monitoring also should be considered in obese and undernourished children, children with severe burns, and those with chronic disease, for which the volume of distribution of the drug can be altered (e.g., cystic fibrosis).

Macrolides

Erythromycin, isolated from *Streptomyces erythreus* found in a soil sample in the Philippines, was the first macrolide and was available for use in 1952. Many natural and semisynthetic erythromycin derivatives have been developed since then, three of which are approved for use in pediatrics: erythromycin, clarithromycin, and azithromycin. Macrolide antibiotics consist of a large lactone ring attached by a glycosidic bond to one or more amino or neutral sugar moieties. Erythromycin and clarithromycin have 14-member lactone rings, whereas azithromycin, an azalide antibiotic that is grouped with the macrolides, has a tertiary amino group inserted in its 15-member ring. In addition to similarities in chemical structure, these macrolides have similar antibacterial spectra, mechanisms of action, and mechanisms of resistance, but they differ in their pharmacokinetic characteristics. Ketolides are a new class of macrolides with in vitro activity against macrolide-resistant gram-positive organisms, including *S. pneumoniae*. Telithromycin received FDA approval in 2004 for use in adults, but use is limited to mild-to-moderate community-acquired pneumonia after increasing reports of hepatotoxicity.[325]

Mechanisms of Action

Macrolide antibiotics reversibly bind to the 50S ribosomal subunit and inhibit protein synthesis. Initial studies suggested that the antibacterial activity of erythromycin usually was bacteriostatic, but against some actively growing, susceptible bacteria, large concentrations of erythromycin were bactericidal.[132] Clarithromycin and azithromycin usually are bacteriostatic, but they are bactericidal against *S. pyogenes*, *S. pneumoniae*, and *H. influenzae*.[324] Macrolides cause dissociation of peptidyl-tRNA from bacterial ribosomes, which results in accumulation of intracellular peptidyl-tRNA and depletion of the free tRNA pool, with toxic effects for bacteria.[298] The specific target appears to be the 23S ribosomal RNA. Macrolides block the entrance to the tunnel in the 50S ribosomal subunit through which many, if not all, nascent peptide chains exit the ribosome. By blocking the exit tunnel, macrolides induce premature dissociation of peptidyl-tRNAs from the ribosome just after initiation of protein synthesis. Erythromycin interferes with binding to the 50S ribosome by chloramphenicol and clindamycin, thus suggesting common or overlapping binding sites for these agents.

Mechanisms of Resistance

Many gram-negative bacteria are inherently resistant to macrolides because of the relative impermeability of their outer membrane. Other bacteria can acquire resistance by production of enzymes that modify and inactivate the macrolide, active efflux of the antibiotic, and alteration of their ribosomal targets.[184] Two mechanisms by which bacteria can alter their ribosomes and acquire macrolide resistance have been identified. High-level resistance because of an altered protein component in domain V of the 50S ribosomal subunit has occurred after a one-step chromosomal mutation. Such resistance has been demonstrated in *M. avium*, *Helicobacter pylori*, *Treponema pallidum*, and *Propionibacterium* spp. Plasmid-mediated macrolide, lincosamide, and streptogramin B (MLS_B) resistance occurs when a single adenine residue within a conserved region of domain V of the nascent 23S rRNA component of the 50S ribosomal subunit is methylated. Such methylation results in an altered common target that confers cross resistance to macrolides (i.e., erythromycin and clarithromycin), azalides (i.e., azithromycin), lincosamides (i.e., clindamycin), and streptogramin B (i.e., quinupristin-dalfopristin).[184] The production of methylases is encoded by a class of genes referred to as *erm* (erythromycin ribosome methylation), nearly 40 of

which have been characterized in a wide range of microorganisms, including gram-positive species, spirochetes, and anaerobes. Twenty-one classes of *erm* genes with less than 80 percent sequence homology have been designated unique letters. Pathogenic bacteria are one of four major classes: bacteria in classes erm(A) and erm(C) typically are in methicillin-resistant or methicillin-susceptible strains of staphylococci, respectively; members of class erm(B) are mostly in streptococci and enterococci; and class erm(F) usually is associated with anaerobic pathogens.[263] These genes are exchanged easily among different strains by plasmids, transposons, or bacterial conjugation. Resistance mediated by erm can be constitutive or inducible. When bacteria with inducible MLS_B resistance are exposed to a macrolide inducer (i.e., erythromycin, clarithromycin, or azithromycin), inactive methylase mRNA undergoes rearrangements that permit ribosomes to translate the methylase coding sequence. The diversity of inducible macrolide-resistant genotypes results in complex phenotypes, particularly among streptococci and enterococci with *erm(B)* genes, whereas constitutive production of a methylase generally confers a predictable high-level cross resistance to all MLS_B antibiotics. Staphylococci that are resistant in vitro to 14- and 15-membered ring macrolides but susceptible to 16-membered ring macrolides, clindamycin, and streptogramins B should routinely undergo further testing with a double-disk diffusion test to screen for an erythromycin-induced, "D"-shaped zone of bacterial inhibition around a clindamycin disk. A positive D-test indicates that the *Staphylococcus* isolate has inducible MLS_B resistance and that use of clindamycin can result in clinical treatment failure, presumably related to selection of constitutive mutants in patients with severe infections and large bacterial inocula.[184] Similar inducible resistance phenotypes may be observed among various strains of streptococci for which the use of clindamycin should be discouraged.

Macrolide resistance associated with active efflux is caused by two classes of pumps: a plasmid-mediated, ATP-binding cassette (ABC) transporter encoded by the *msr(A)* gene and found in *Staphylococcus* spp., and a protein of the major facilitator superfamily found in streptococci and enterococci and encoded by the *mef(A)* gene. The MsrA pump confers a macrolide and streptogramin B (MS_B) pattern of resistance that can be distinguished from the MLS_B-inducible phenotype by the double-disk diffusion D-test. The Mef(A) pump affects only 14- and 15-membered ring macrolides (M phenotype).[184] Less commonly, bacteria produce enzymes that inactivate macrolides, including acetyltransferases, esterases, phosphotransferases, or glycosylases found in some strains of Enterobacteriaceae, but macrolides are not used to target these pathogens. Therefore, this mechanism of low-level resistance is not clinically important.[263] A causal association between erythromycin resistance and antibiotic use, probably mediated by selection pressure, was suggested by a nationwide epidemiologic study in Finland in which reduction of the use of erythromycin over the course of time was associated with a steady decline in erythromycin resistance among *S. pyogenes* isolates from throat swabs and pus specimens.[283] Conversely, increased consumption of macrolides in Spain since 1995 was related to an increase in macrolide resistance.[124] Pneumococcal resistance to macrolides has also increased to about 35 percent as reported in prospective multicenter monitoring studies. In the United States, 6 percent of the macrolide-resistant isolates exhibited low-level erythromycin resistance by expression of the *mef(A)* gene and about 20 percent expressed the *mef(A)* and the *erm(B)* gene, resulting in high-level resistance.[325,154]

In Vitro Activity

Erythromycin is effective in vitro against a diverse group of microorganisms, including *Bacteroides* spp., *Bordetella pertussis*, *Chlamydophila* spp., *Corynebacterium diphtheriae*, *H. pylori*, the bacterium of legionnaires' disease *(Legionella pneumophila)*, mycoplasmas (*Mycoplasma pneumoniae* and *Ureaplasma urealyticum*), spirochetes *(T. pallidum)*, and anaerobic and aerobic gram-positive cocci (*S. pneumoniae*, *S. pyogenes*, and penicillinase-producing and non–penicillinase-producing strains of oxacillin-susceptible *S. aureus*). Erythromycin is active against *Campylobacter jejuni*, *N. meningitidis*, *N. gonorrhoeae*, and, to a lesser extent, *H. influenzae*. Macrolide resistance among diverse pathogens is increasing worldwide, and the clinical consequences are topics of active research.[116,149,175]

The newer macrolides have spectra of activity similar to that of erythromycin. In contrast to erythromycin, clarithromycin has equivalent or greater activity against *M. catarrhalis*, *H. influenzae*, *M. pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia trachomatis*, *L. pneumophila*, *U. urealyticum*, and *N. gonorrhoeae*. Clarithromycin is two to four times more active against most erythromycin-susceptible streptococci and staphylococci. However, pneumococci that are resistant to erythromycin (≤48% in certain regions[176]) also are resistant to clarithromycin and azithromycin; rates of macrolide resistance among pneumococci tend to correlate with rates of penicillin resistance.[324] Clarithromycin also has activity against organisms that are resistant to erythromycin, including *H. pylori*, *Toxoplasma gondii*, *Mycobacterium leprae*, MAC, and *Mycobacterium chelonae*.

In contrast to erythromycin, azithromycin has less activity against gram-positive bacteria, including *S. pneumoniae*, but has better activity against gram-negative bacteria, including *Vibrio cholerae* and some Enterobacteriaceae such as *Shigella* spp. The in vitro activity of azithromycin against *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila* is similar to that of erythromycin and clarithromycin. Azithromycin is more active than erythromycin against *C. trachomatis* and *U. urealyticum* and twofold to eightfold more active than erythromycin or clarithromycin against *M. catarrhalis*, *H. influenzae*,[21,208] *N. gonorrhoeae*, and *H. ducreyi*. Azithromycin has activity against *T. gondii* and, although less than that of clarithromycin, against MAC organisms. Azithromycin and clarithromycin are highly effective in vitro against *Borrelia burgdorferi*, *Bartonella henselae*, and *Bartonella quintana*.

Pharmacokinetics

The macrolides differ in pharmacokinetic properties (Table 235-8). Clarithromycin[131] and azithromycin[122] are gastric acid–stable and relatively well absorbed from the

¶C_{max} = peak serum concentration.

gastrointestinal tract, whereas erythromycin is acid-labile and absorption varies with the oral preparation. Macrolides undergo metabolism by the hepatic microsomal cytochrome P (CYP)450 system. Erythromycin and clarithromycin, but not azithromycin, are inhibitors of the CYP450 enzyme system (CYP3A and CYP1A subclasses) and can interact with other drugs that are metabolized by this system.[239] Most of the metabolites are inactive, with the exception of 14-(R)-hydroxyclarithromycin, an active metabolite that can act additively or synergistically with clarithromycin. The lipophilic macrolides are distributed well in tissues and fluids, except CSF. High intracellular concentrations are achieved, but, with the exception of azithromycin, the macrolides rapidly diffuse out of cells when extracellular concentrations are low. Clarithromycin and azithromycin are transported actively into leukocytes and macrophages. High concentrations of clarithromycin are present in the nasal mucosa, tonsils, and pulmonary epithelial lining fluid and alveolar cells.[76] Tissue concentrations of clarithromycin and azithromycin exceed those found in plasma by 2 to 20 times and 10 to 100 times, respectively. The favorable cellular penetration probably contributes to the efficacy of clarithromycin and azithromycin in the treatment of intracellular pathogens. Furthermore, sustained intracellular concentrations of azithromycin facilitate short-course therapy for pharyngitis and acute otitis media and single-dose therapy for chlamydial STDs.[122] Isolated cases of intravascular bacterial infections developing during macrolide therapy for focal infections have been reported and evoke concern that, despite elevated tissue concentrations, low serum concentrations may not treat systemic infections consistently.[175] Erythromycin and azithromycin are eliminated primarily by biliary excretion, whereas clarithromycin is excreted predominantly by the kidneys. A reduction in the dosage of clarithromycin may be required in patients with moderate-to-severe renal insufficiency. Because of their longer serum half-life, azithromycin and clarithromycin can be administered in a once- and twice-daily regimen, respectively, in contrast to the three- or four-times-daily dosing necessary for erythromycin.

Because erythromycin base is unstable at the low pH of the stomach, better-absorbed products were prepared by the addition of protective enteric coating or by alteration of the chemical structure through the formation of salts and esters. Salt and ester derivatives include ethylsuccinate or propionate (esters), stearate (a salt), and estolate (salt of an ester). Estolate provides the highest concentration of antimicrobial activity in serum, but controversy continues about which preparation provides the most biologically active drug at the site of infection. Because the base is the active component, all erythromycin preparations must be hydrolyzed to the base after absorption. Formulations of erythromycin base include tablets, delayed-release tablets, and capsules. Erythromycin estolate is marketed in capsule form, suspension, and tablets. Erythromycin ethylsuccinate is available in suspension, tablets, and chewable tablets. Erythromycin stearate is in tablet form only in the United States. Parenteral preparations of erythromycin include the lactobionate and gluceptate derivatives. Intramuscular administration of these forms is painful and should be avoided. Clarithromycin can be taken without regard to food, whereas azithromycin should be taken at least 1 hour before or 2 hours after a meal. Clarithromycin is available in suspension (125 and 250 mg/5 mL) and in tablet (250 and 500 mg) forms. Azithromycin is manufactured in 250-mg capsules and as a suspension (100 and 200 mg/5 mL). Azithromycin for intravenous injection has not been approved for use in children younger than the age of 16 years, although pharmacokinetic data are available.[151]

Indications for Use

Erythromycin is approved for the treatment of chlamydial conjunctivitis, pneumonia and urethritis, mycoplasmal and *Legionella* pneumonia, group A streptococcal sinusitis and pharyngitis, mild pneumococcal pneumonia, uncomplicated skin and soft tissue infections caused by susceptible organisms, diphtheria, pertussis, erythrasma, listeriosis, and nongonococcal urethritis and as

second-line therapy for gonococcal urethritis. It also is approved for use as a preoperative bowel preparation, for penicillin-allergic persons as prophylaxis for bacterial endocarditis and rheumatic fever, and for the treatment of syphilis in nonpregnant individuals. In the context of increasing prevalence of erythromycin resistance among common pathogens, newer macrolides or other classes of antibacterial agents may be more effective for certain infections.

Clarithromycin is approved for treatment of bacterial exacerbations of bronchitis; streptococcal pharyngitis; mycoplasmal, chlamydial, and pneumococcal community-acquired pneumonia; acute maxillary sinusitis; and uncomplicated skin and soft tissue infections caused by susceptible bacteria. However, increasing rates of clarithromycin resistance among common pathogens of the respiratory tract and skin structures have been associated with treatment failure.[111,149] Clarithromycin and amoxicillin or metronidazole in combination with bismuth compounds, H_2-receptor antagonists, or proton pump inhibitors are recommended for the treatment of H. pylori–associated peptic ulcer disease. Clarithromycin also is approved for prophylaxis of disseminated MAC infections in children and adults with advanced human immunodeficiency virus (HIV) infection. Furthermore, clarithromycin, in combination with other antimycobacterials, is an effective therapeutic agent for disseminated MAC infections, but safety has not been established for this indication in children younger than 20 months of age. The safety and efficacy of clarithromycin have not been established for infants younger than 6 months of age.

In adults, azithromycin is approved for treatment of bacterial exacerbations of bronchitis; chlamydial and gonococcal cervicitis and urethritis; chancroid; streptococcal tonsillitis and pharyngitis; uncomplicated skin and soft tissue infections caused by susceptible bacteria; and acute otitis media and pneumonia caused by *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae*. It also is approved in adults for prophylaxis of disseminated MAC infection in patients with advanced HIV infection. Pediatric indications include group A streptococcal pharyngitis; acute otitis media caused by *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae;* and mild community-acquired pneumonia caused by *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, or *C. pneumoniae.*

Five-day regimens have been approved for the treatment of pharyngitis (12 mg/kg/day) and otitis media (single dose of 10 mg/kg followed by 5 mg/kg/day). A randomized clinical trial comparing azithromycin with high-dose (90/6.4 mg/kg/day) amoxicillin-clavulanate for the treatment of acute otitis media revealed that the lactam–containing regimen achieved superior bacteriologic and clinical outcomes for all bacterial pathogens, including penicillin-resistant *S. pneumoniae* and *H. influenzae.*[137] Consequently, consensus guidelines do not recommend azithromycin or clarithromycin for empirical treatment of acute otitis media unless the patient has a type 1 hypersensitivity reaction to penicillins.[10] Shorter courses of azithromycin for uncomplicated group A streptococcal pharyngitis (20 mg/kg/day for 3 days)[73] or acute otitis media (single dose of 30 mg/kg)[13] have been found to be equally effective as standard therapy but have not been approved by the FDA. A clinical study suggested that a 5-day course of azithromycin for localized cervical lymphadenopathy caused by *B. henselae* (cat scratch disease) is beneficial.[26] The CDC recommends azithromycin for the treatment of chlamydial genital infections, nongonococcal urethritis, and chancroid (a single 20-mg/kg dose; maximum dose, 1 g)[316] and for prophylaxis of disseminated MAC infection in HIV-infected children.[163] The current American Thoracic Society and Infectious Disease Society of America guidelines for treatment and prevention of nontuberculous mycobacteria recommend a combination regimen including a macrolide (either clarithromycin or azithromycin) with ethambutol and rifampin for patients with nodular, bronchiectatic, or fibrocavitary lung disease caused by MAC.[126] Data supporting the use of azithromycin for treatment of ophthalmia neonatorum caused by *C. trachomatis* are limited to one small study in which a single oral dose of 20 mg/kg/day for 3 days appeared effective.[316]

Although the safety and efficacy of azithromycin and clarithromycin have not been determined for infants younger than 6 months of age (or for pregnant or lactating women), these antimicrobials are recommended as first-line agents for treatment and postexposure prophylaxis of pertussis in individuals older than the age of 1 month, based on their in vitro effectiveness, safety and efficacy in older children, and more convenient dosing schedule. Duration of therapy or prophylaxis for pertussis is 14 days for erythromycin (40 to 50 mg/kg/day in four divided doses), 7 days for clarithromycin (15 mg/kg/day in two divided doses), and 5 days for azithromycin (10 mg/kg as single daily doses for infants <6 months of age; 10 mg/kg as a single dose on day 1, then 5 mg/kg/day on days 2 to 5 for infants and children ≥6 months of age). Azithromycin is the preferred macrolide for postexposure prophylaxis and treatment of pertussis in neonates because it has fewer adverse effects in contrast to erythromycin and no association with infantile hypertrophic pyloric stenosis.[304] A multicenter study established that children with cystic fibrosis chronically infected with *P. aeruginosa* had significantly improved lung function and clinical end points associated with azithromycin treatment three times per week.[273] This effect may not persist. Studies in endemic regions showed that a single dose of azithromycin is as effective as standard therapy with erythromycin for treatment of cholera in children.[171] A 5-day course of azithromycin (20 mg/kg/day; maximum dose, 1 g) is an effective treatment for uncomplicated typhoid fever in children and adolescents.[113] One to six doses of azithromycin for trachoma have been shown to be equivalent to prolonged topical treatment with oxytetracycline polymyxin ointment.[87]

Adverse Effects

The macrolides usually are well tolerated and relatively safe. The most common adverse effect is gastrointestinal disturbance, which can occur with the administration of any macrolide but is associated most commonly with the use of erythromycin. It is a dose-related phenomenon. Because it acts as a motilin receptor agonist,

gastrointestinal symptoms (i.e., nausea, vomiting, diarrhea, flatulence, and abdominal cramps) can occur with orally or parenterally administered erythromycin. Enteric coating of erythromycin does not decrease the incidence. Rapid intravenous infusions of erythromycin can result in thrombophlebitis. Cholestatic hepatitis is an unusual, but serious, macrolide toxicity. It occurs more commonly in adults and possibly in pregnant women and is associated most frequently with the estolate preparation.[51] The onset typically begins approximately 16 days after initiation of therapy and is manifested as fever, pruritus, jaundice, elevated liver function tests, and, occasionally, rash, leukocytosis, and eosinophilia. Signs and symptoms resolve after discontinuation of the macrolide but recur with subsequent therapy. Transient hearing loss has been described after the administration of large dosages of erythromycin lactobionate. Torsade de pointes is an uncommon reaction to intravenous infusions of erythromycin. A sevenfold increase in the rate of infantile hypertrophic pyloric stenosis was temporally associated with and probably causally related to the prophylactic use of erythromycin in neonates during a pertussis outbreak in a community hospital.[141] Gastrointestinal disturbances occur less frequently with clarithromycin and azithromycin, principally because lower dosages are required for effective therapy. Postmarketing experience with the use of intravenous azithromycin reported two cases of infantile pyloric stenosis.

A common and potentially serious toxicity is that of drug interactions.[239] Macrolides are metabolized by hepatic microsomal CYP450 enzymes. Drug interactions can occur during concomitant therapy with two or more drugs that undergo hepatic microsomal P450 metabolism. One proposal for this drug interaction suggests that the macrolide is N-demethylated to a nitrosoalkane that interacts with and inactivates the microsomal enzyme. Toxicity can occur because of interference with metabolism and consequent accumulation of the second drug. The ability to inactivate the enzyme varies with each macrolide; erythromycin is a more potent inhibitor than is clarithromycin. Azithromycin has not been associated yet with nitrosoalkane formation and resulting drug interactions, but caution should be exercised with concomitant administration of warfarin, digitoxin, and antacids. Drugs with which macrolides can interact include astemizole, benzodiazepines, buspirone, carbamazepine, cimetidine, cisapride, cyclosporine, digoxin, methylprednisolone, rifampin, tacrolimus, terfenadine, theophylline, triazolam, verapamil, warfarin, zidovudine, and certain protease inhibitors, among others.[239]

Chloramphenicol

Chloramphenicol, originally derived from *Streptomyces venezuelae* obtained from soil near Caracas, Venezuela, in 1947, now is prepared synthetically. It is a chemically unique agent that contains an aromatic nitro group, an N-dichloroacetyl substituent, and two chiral centers. The availability of less toxic and equally or more effective agents has limited the usefulness of chloramphenicol in the United States.

Mechanisms of Action

Chloramphenicol reversibly binds to the 50S subunit of 70S bacterial ribosomes and thereby inhibits protein synthesis. The mechanism of action involves suppression of peptidyltransferase activity, with a resultant inability to form peptide bonds and elongate the peptide chain.[282,319] Because the ribosomal binding sites of chloramphenicol overlap with those of macrolides, clindamycin, and linezolid, concomitant use of these antibiotics can result in antagonism and should be avoided. Chloramphenicol usually is bacteriostatic, but it can be bactericidal when high concentrations are achieved against highly susceptible organisms such as meningococci and *H. influenzae*.

Mechanisms of Resistance

The most common mechanism of acquired resistance is plasmid-mediated production of chloramphenicol acetyltransferases (CATs), which acetylate chloramphenicol and render it unable to bind to the ribosomal target. Numerous CAT genes encode classic (type A) or novel (type B) CATs and may be associated with multidrug resistance phenotypes. This resistance has been documented in many different genera of bacteria, including *H. influenzae*, members of the Enterobacteriaceae, *Neisseria*, streptococci, and *S. aureus*. Less commonly, multiple specific or multidrug transporter mechanisms (efflux pumps) and chromosomal or plasmid-mediated alterations in permeability have resulted in chloramphenicol resistance in a wide range of bacteria, including *B. cepacia*, *E. coli*, *H. influenzae*, *P. aeruginosa*, and *S. typhi* (in the absence of OmpF protein). More recently described alterations in bacterial 23S rRNA have been associated with chloramphenicol resistance by inducing frameshift mutations and readthrough of stop codons.[302] In addition, isolated cases of resistance in *Bacillus subtilis* because of altered ribosomes and in anaerobes because of inactivation of chloramphenicol by nitroreduction have been reported.[282]

In Vitro Activity

Chloramphenicol has broad-spectrum activity against aerobic and anaerobic gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, spirochetes, and rickettsiae.[260] It is bactericidal against susceptible strains of *H. influenzae*, *N. meningitidis*, and penicillin-susceptible *S. pneumoniae*, whereas it is bacteriostatic against most other susceptible microorganisms.[253] Frequently susceptible aerobic gram-positive cocci include groups A and B β-hemolytic streptococci, viridans streptococci, and penicillin-susceptible pneumococci. Because penicillin-resistant pneumococci may be tolerant to chloramphenicol in vitro, meaning that concentrations of drug necessary to kill these pneumococci are approximately 30-fold higher than necessary to inhibit the organism, verifying chloramphenicol susceptibility by MBC testing is prudent, especially when treating meningitis.[114] Usually, chloramphenicol is active against oxacillin-susceptible *S. aureus*, but susceptibility patterns vary with the use of chloramphenicol, and more suitable alternatives for

therapy exist. Susceptible gram-positive bacilli include *Bacillus* spp., *L. monocytogenes*, *C. diphtheriae*, *Clostridium* spp., and *Eubacterium*. Most *N. meningitidis* and *N. gonorrhoeae* organisms are susceptible.[161] However, several high-level chloramphenicol-resistant strains of meningococcus belonging to serogroup B were isolated from the CSF of children in Vietnam.[115] The susceptibility of Enterobacteriaceae, including for *Salmonella* and *Shigella* spp., is variable. Other gram-negative bacilli frequently susceptible to chloramphenicol include *B. pertussis*, *B. cepacia*, *Brucella* spp., *C. jejuni*, *F. tularensis*, *H. influenzae*, *Pasteurella multocida*, *Pseudomonas pseudomallei*, *V. cholerae*, and *Y. pestis*. Virtually all obligate anaerobes are susceptible.

Pharmacokinetics

After oral administration, absorption of chloramphenicol is rapid and complete. Bioavailability is approximately 80 percent after oral administration, but it is only 70 percent after an intravenous dose because approximately 30 percent of the parenterally administered dose is excreted in urine before hydrolysis of the succinate ester to the active form. Intramuscular injection results in peak serum concentrations comparable to those achieved after intravenous infusion. Because of its lipid solubility, chloramphenicol diffuses rapidly and widely into tissues and fluids.[260] The highest concentrations are achieved in the liver and kidneys, with high concentrations present in urine, and therapeutic concentrations are achieved in aqueous and vitreous humor. CSF concentrations range from 21 to 50 percent and from 45 to 89 percent of serum values in the presence of uninflamed and inflamed meninges, respectively. Brain tissue concentrations exceed those in plasma. Chloramphenicol also is distributed into pleural, ascitic, and synovial fluids, as well as saliva and breast milk. Protein binding ranges from 32 percent in premature newborns to 50 to 60 percent in adults. Chloramphenicol palmitate and chloramphenicol sodium succinate are esterified prodrugs of chloramphenicol. Orally administered chloramphenicol palmitate is hydrolyzed to active drug by pancreatic esterases in the small intestine before absorption. After intravenous infusion, chloramphenicol sodium succinate is hydrolyzed rapidly to active drug in the kidneys, liver, and lungs. Ninety percent of active chloramphenicol is conjugated to the inactive glucuronide primarily by the liver. Immature metabolic function of the liver in the fetus and newborn results in inadequate conjugation of chloramphenicol, with subsequent accumulation of toxic concentrations of active drug. Peak serum concentrations in children after a dose of 25 mg/kg range from 19 to 28 μg/mL, whereas in adults receiving doses of 12.5 mg/kg, peak serum values of 11 to 18 μg/mL can be achieved. Although metabolized to inactive metabolites by the liver, chloramphenicol is excreted by the kidneys: 5 to 10 percent as active drug and 80 percent as inactive metabolites. The elimination half-life is significantly longer but variable, and serum concentrations are unpredictable in neonates.[260] Dosage adjustments should be considered in persons with severe hepatic insufficiency or combined hepatic and renal insufficiency and in patients receiving drugs that compete for hepatic CYP450 oxidases, such as phenytoin, phenobarbital, and rifampin. Chloramphenicol is not removed by peritoneal dialysis or hemodialysis, but charcoal hemoperfusion may lower serum concentrations.

Available formulations of chloramphenicol include chloramphenicol palmitate in an oral suspension of 150 mg base/5 mL, 250-mg capsules of chloramphenicol base, and chloramphenicol sodium succinate for parenteral use. Other formulations include 1 percent cream for topical use, 0.5 percent otic solution, 0.5 percent ophthalmic solution, and 1 percent ophthalmic ointment.

Indications for Use

Because of its low therapeutic-toxic index, use of chloramphenicol should be reserved for serious infections for which less toxic agents are ineffective or contraindicated. In some developed countries, chloramphenicol has been replaced by third-generation cephalosporins for the treatment of bacterial meningitis and by clindamycin or metronidazole for the treatment of anaerobic infections. Ceftriaxone is a safe and effective alternative to (1) chloramphenicol for the treatment of acute typhoid fever[216] and (2) long-acting oily chloramphenicol for epidemic meningococcal meningitis in sub-Saharan Africa.[225] Infections for which chloramphenicol may be indicated include pneumococcal, meningococcal, and *H. influenzae* meningitis in β-lactam–allergic individuals; brain abscesses caused by susceptible anaerobic bacteria resistant to other agents; acute typhoid fever; and rickettsial infections (i.e., typhus, Q fever, Rocky Mountain spotted fever). Doxycycline is preferred for treatment of rickettsial infections in children, even those younger than 9 years of age. Chloramphenicol is not indicated for the treatment of trivial infections, prophylaxis of infections, or treatment of typhoid carrier states.

Adverse Effects

Hematologic adverse events associated with the use of chloramphenicol include hemolytic anemia in patients with the Mediterranean type of glucose-6-phosphate dehydrogenase deficiency, reversible bone marrow suppression, and aplastic anemia. Reversible bone marrow suppression is a dose-related phenomenon. It usually occurs when serum concentrations exceed 25 μg/mL, as can be seen when administering large dosages, during prolonged therapy, or in patients with impaired liver function. Although mammalian cells contain 80S ribosomes, rather than the 70S ribosomes found in prokaryotes, mitochondria possess 70S ribosomes. A proposed mechanism of myelosuppression involves inhibition of mitochondrial protein synthesis in host bone marrow stem cells.[282] Dose-related bone marrow suppression is manifested by peripheral anemia with or without reticulocytopenia, leukopenia, and thrombocytopenia and bone marrow findings of increased cellularity, cytoplasmic vacuolization, and maturation arrest of erythroid and myeloid precursors. In contrast, aplastic anemia is a rare, often fatal idiosyncratic reaction that is unrelated to the dosage, duration, or route of therapy. The pathogenesis

is understood less well but possibly is related to DNA damage from toxic metabolites of chloramphenicol produced by nitroreduction.[319] The incidence ranges from 1/25,000 to 40,000 courses. Onset can begin during therapy but typically occurs weeks to months or, rarely, years after therapy has been discontinued. Manifestations include peripheral pancytopenia and hypoplastic or aplastic marrow.

Gray syndrome, or gray baby syndrome, is a rare but serious and potentially fatal adverse event that usually occurs in newborn and young infants, but has been described in older children and adults with hepatic insufficiency. Most often, this syndrome occurs when serum chloramphenicol concentrations exceed 40 μg/mL and is thought to be a result of inhibition of mitochondrial electron transport in liver, skeletal muscle, and myocardium. The onset typically begins 2 to 9 days after initiating therapy. Manifestations include hypothermia, tachypnea, blue-gray skin color (cyanosis), abdominal distention, emesis, unresponsiveness, and refractory metabolic acidosis that can progress to vasomotor collapse and death within 2 days.

Uncommon side effects include hypersensitivity reactions such as drug fever, rash, urticaria, anaphylaxis, and a Herxheimer-like reaction during therapy for syphilis, typhoid fever, and brucellosis; gastrointestinal symptoms, including nausea, emesis, diarrhea, and an unpleasant taste; and neurologic symptoms such as peripheral neuritis, headache, mental confusion, and optic neuritis, the last of which may not be entirely reversible.

Chloramphenicol can inhibit the metabolism of other drugs metabolized by the hepatic microsomal CYP450 system and thus result in the accumulation of alfentanil, barbiturates, cyclophosphamide, phenytoin, antidiabetic sulfonylureas (more common with chlorpropamide and tolbutamide than with glyburide and glipizide), and warfarin during concomitant therapy.[6] Because some agents such as rifampin, phenobarbital, and phenytoin are potent inducers of hepatic microsomal enzymes, when they are given concomitantly with chloramphenicol, metabolism is enhanced, and serum concentrations of active chloramphenicol are reduced. Other drug interactions include a reduction in the effectiveness of estrogen-containing oral contraceptives when used concurrently with chloramphenicol and a delay in the response to vitamin B_{12}, folic acid, and iron. A mild disulfiram-like reaction can occur when alcohol is ingested during chloramphenicol therapy. Both cimetidine and chloramphenicol have rare associations with aplastic anemia; a few reports of concomitant use resulting in aplastic anemia have been documented, thus suggesting a potential for additive or synergistic risk. Concomitant acetaminophen therapy has been the subject of controversy; some studies suggest that coadministration can prolong the elimination half-life of chloramphenicol, but other reports suggest no effect or enhanced metabolism of chloramphenicol. Lincosamides and macrolides can have an antagonistic effect when they are administered concurrently with chloramphenicol because of competition for ribosomal binding sites. Chloramphenicol is physically incompatible in solution with many drugs, including tetracyclines and vancomycin.

Because of considerable variability in serum chloramphenicol concentrations, the narrow therapeutic-toxic index, and the potential for drug interactions, monitoring serum concentrations of chloramphenicol and peripheral blood counts during therapy is prudent, particularly for neonates.

Tetracyclines

Chlortetracycline (Aureomycin) was the first natural tetracycline discovered when isolated from *Streptomyces aureofaciens* in 1948.[105] Many tetracyclines have been developed since then. Those currently marketed include the natural agents tetracycline, oxytetracycline, and demeclocycline and the semisynthetic agents doxycycline and minocycline. Their basic structure consists of a hydronaphthacene nucleus with four fused rings. They differ from each other biochemically by substituent variations at carbons 5, 6, or 7. Their mechanisms of action and mechanisms of resistance, as well as their spectra of activity, are similar, but the analogs differ in the degree of activity and pharmacokinetic properties. Tigecycline is a novel intravenously administered glycylcycline that is related structurally to minocycline. It is approved for use in adults with complicated skin and skin structure infections, community-acquired pneumonia, and complicated intra-abdominal infections. It is bacteriostatic, with improved activity against multidrug-resistant bacteria, and it has no cross resistance with other classes of antimicrobial agents. Tigecycline has activity against *S. aureus* (including MRSA), enterococci (including VRE), and multidrug-resistant gram-negative bacteria, including ESBL-producing enteric gram-negative organisms. It is also active against rapidly growing, nontuberculous mycobacteria. It is not recommended for serious infections caused by *P. aeruginosa*.[234]

Mechanisms of Action

Tetracyclines passively diffuse through outer-membrane porins and then traverse the cytoplasmic membrane by energy-dependent active transport. Tetracyclines are actively concentrated by most bacterial cells, but not by mammalian cells, a characteristic that explains the selective action of these drugs against bacteria. Tetracyclines are bacteriostatic agents that reversibly bind to the 30S subunit of 70S bacterial ribosomes and inhibit protein synthesis. Because attachment of aminoacyl-tRNA to the ribosome acceptor site is prevented, the bacteria are unable to add amino acids to the growing peptide chain.

Mechanisms of Resistance

In many bacteria, including members of the Enterobacteriaceae, *P. aeruginosa*, staphylococci, streptococci, and *Bacteroides*, resistance to tetracyclines has developed. Resistance in most bacteria results from the acquisition of new genes often associated with mobile elements such as plasmids or transposons, but it also can be chromosomally mediated. The genes encoding for acquired resistance are called tet (tetracycline)-resistance or otr

(oxytetracycline)-resistance determinants. Resistance to one tetracycline usually implies resistance to all; however, many tetracycline-resistant bacteria are susceptible to doxycycline, minocycline, or both. At least 38 acquired tetracycline and oxytetracycline resistance genes have been identified that mediate (1) energy-dependent efflux of tetracycline (the most common type of resistance mechanism), (2) protection of the ribosomes from the action of tetracycline, or (3) enzymatic inactivation of tetracycline.[262] Tet genes that encode membrane efflux proteins are different in gram-positive and gram-negative bacteria. Efflux has been found in a wide range of bacteria, including *Acinetobacter*, *Aeromonas*, *Chlamydia*, the Enterobacteriaceae, *Haemophilus*, *Moraxella*, *Neisseria*, *Pseudomonas*, staphylococci, *Stenotrophomonas*, *V. cholerae*, and others. Less commonly, ribosomal protection by a soluble ribosomal protection protein encoded by different tet and otr genes has been found in a wide variety of aerobic and anaerobic gram-positive and gram-negative bacteria. The precise mechanism by which ribosomal protection protein mediates resistance to tetracyclines is being investigated. Researchers have hypothesized that these protection determinants produce allosteric disruption of the primary tetracycline binding site that causes the tetracycline molecules to be released from the ribosome. Enzymatic inactivation of tetracycline, encoded for by other tet genes, has been demonstrated in in vitro studies of *Bacteroides*, and *E. coli*, but the clinical significance has not been established.[262] Susceptibility of staphylococci to this class of agents typically is tested using tetracycline. However, this approach may overestimate the prevalence of resistance to doxycycline and minocycline. Although the prevalence of tetracycline resistance remains relatively low among CAMRSA isolates, resistance in some strains has been associated with tetK, a finding indicating that doxycycline and minocycline may be effective treatment options. However, because data are sparse on clinical outcomes associated with the use of minocycline or doxycycline to treat infections caused by tetracycline-resistant *S. aureus* strains, these agents are not recommended.[123] Tigecycline overcomes two major resistance mechanisms, including drug efflux and protection of ribosomes.

In Vitro Activity

Tetracyclines are broad-spectrum antibiotics with activity against aerobic and anaerobic gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, rickettsiae, and spirochetes. Activity against gram-negative bacteria has been limited by the emergence of tetracycline-resistant strains. Most *P. aeruginosa* and many *Shigella* and *Salmonella* organisms are resistant. Penicillin-susceptible strains of *N. gonorrhoeae* and *N. meningitidis* usually are susceptible to tetracyclines, but penicillin-resistant strains of *N. gonorrhoeae* are not. Gram-negative organisms with continued susceptibility to tetracyclines include *Aeromonas hydrophila*, *Brucella*, *Campylobacter*, some *Haemophilus* organisms, *Helicobacter*, *P. multocida*, *Plesiomonas shigelloides*, and *Vibrio*. Tetracyclines are active against some gram-positive bacilli, including *A. israelii*, *B. anthracis*, many clostridia, *Listeria*, and *Nocardia*. Tetracyclines have excellent activity against *C. pneumoniae*, *M. pneumoniae*, and rickettsiae. Other organisms for which tetracyclines have activity include *Mycobacterium marinum* and *Borellia burgdorferi*. The more lipophilic agents doxycycline and minocycline generally are more active than the others. Minocycline has excellent activity against susceptible staphylococci, and both doxycycline and minocycline are more active than tetracycline against *S. aureus* and some streptococci, but they have no activity against enterococci and group B streptococci. Because of extensive plasmid-mediated resistance in pneumococci, therapy with tetracycline should be avoided. Doxycycline and minocycline are more active in vitro than the other agents against anaerobic bacteria, but alternative antimicrobials are preferred for anaerobic infections because more than 50 percent of *B. fragilis* isolates are resistant, and susceptibility among other anaerobes is highly variable.[261]

Pharmacokinetics

The five tetracycline compounds available for systemic use can be classified by duration of activity: tetracycline and oxytetracycline are short-acting agents, demeclocycline is intermediate acting, and doxycycline and minocycline are long-acting agents (Table 235-9). Oral

TABLE 235-9 **Pharmacokinetics of Tetracyclines**

Drug	Oral Absorption (%)	Protein Binding (%)	Primary Route of Excretion	Approximate Half-Life* (hr)
Short Acting				
Oxytetracycline	58	35	Renal	6-10
Tetracycline	75-77	65	Renal	6-11
Intermediate Acting				
Demeclocycline	66	91	Renal	10-17
Long Acting				
Doxycycline	90-100	93	Biliary	12-22
Minocycline	90-100	76	Biliary	11-23

Modified from U.S. Dispensing Information. *Information for the health care professional.* Vol. 1, Thomson Micromedex, 2006.
*Normal renal function.

administration is the preferred route because thrombophlebitis is associated with intravenous infusion and pain is associated with intramuscular injections. Oral absorption ranges from 58 percent for the short-acting agents to 100 percent for the long-acting ones. The presence of food decreases the absorption of demeclocycline, oxytetracycline, and tetracycline. Because tetracyclines form insoluble complexes in the gut with aluminum, calcium, iron, magnesium, zinc, and other bivalent and trivalent cations, coadministration with milk and other dairy products, antacids, calcium or iron supplements, cathartics, and other agents can reduce absorption and should be avoided. Differences in lipid solubility affect penetration of tissues by the various tetracyclines. All agents readily penetrate many tissues and fluids, among which are pleural, ascitic, and synovial fluids, sinus secretions, sputum, bone, teeth, and breast milk. Tetracyclines can cross the placenta. The highest concentrations are achieved in bile and can exceed serum concentrations by 5 to 20 times. Therapeutic concentrations of doxycycline can be achieved in tonsillar and pulmonary tissues, the eye, and the prostate, and high concentrations are achieved in myometrial and endometrial tissue and the kidney.[274] Minocycline penetrates into sputum, saliva, and tears, as well as into cells of the vestibular apparatus.[157] Minocycline is biotransformed to inactive metabolites by the liver; the other tetracyclines are not metabolized, although whether doxycycline is metabolized is not clear. Oxytetracycline, demeclocycline, and tetracycline are eliminated unchanged in urine. Approximately 10 percent of minocycline is excreted unchanged in urine, 20 to 35 percent is excreted unchanged in feces, and the remainder is excreted as inactive metabolites in urine and feces. Thirty to 40 percent of doxycycline is excreted in urine; the remainder is excreted by the biliary tract and by diffusion through the intestinal wall, where some of it is chelated and prevented from reabsorption and enterohepatic cycling. Dosing of short- and intermediate-acting tetracyclines must be adjusted for renal failure.

Systemic formulations available in the United States include tablets, capsules, delayed-release capsules, and suspensions for many of the tetracyclines, as well as parenteral preparations of doxycycline, minocycline, and oxytetracycline. Ophthalmic and topical preparations also are available. Tigecycline is available only as a parenteral formulation.

Indications for Use

With few exceptions, tetracyclines no longer are the drugs of choice for many infections because of the availability of cephalosporins and semisynthetic penicillins with equivalent or greater activity and less frequent side effects. As a result of the potential for dental toxicity, tetracyclines are not recommended for use in children younger than 9 years of age, except for specific infections for which alternative therapy is potentially more toxic, such as chloramphenicol for Rocky Mountain spotted fever and ehrlichiosis.[2] Approved indications in the United States include treatment of actinomycosis, anthrax, brucellosis, inclusion conjunctivitis, psittacosis, Q fever, rickettsialpox, Rocky Mountain spotted fever, typhus, relapsing fever, syphilis, trachoma, yaws, and Vincent necrotizing gingivostomatitis caused by *Fusobacterium*, as well as infections caused by *Bacteroides* spp., *Bartonella bacilliformis*, *Campylobacter fetus*, *F. tularensis*, *M. pneumoniae*, *V. cholerae*, *Y. pestis*, and others. Because of its excellent tissue penetration and spectrum of activity, doxycycline is the preferred tetracycline for treatment of atypical pneumonia caused by *M. pneumoniae* and *C. pneumoniae*, intra-abdominal or pelvic infections, and several STDs, including granuloma inguinale, chlamydial infections, *U. urealyticum* infection, nongonococcal urethritis, pelvic inflammatory disease (plus cefoxitin, ampicillin-sulbactam or single-dose ceftriaxone with or without metronidazole), acute epididymitis (plus ceftriaxone), proctitis (plus ceftriaxone), and prostatitis.[316] Doxycycline is an alternative drug for (nonpregnant) penicillin-allergic patients with primary, secondary, or late latent syphilis. Although minocycline is effective in eradicating nasopharyngeal carriage of meningococcus, its potential for vestibular toxicity precludes its use for this purpose. For prevention of Lyme disease after a recognized tick bite, a single dose of doxycycline may be offered to adults (200 mg dose) and to children older than 8 years of age (4 mg/kg, up to a maximum dose of 200 mg), provided the following criteria are met: (1) the attached tick can be identified reliably as an adult or nymphal *Ixodes scapularis* tick that is estimated to have been attached for more than 36 hours on the basis of the degree of engorgement of the tick, (2) prophylaxis can be started within 72 hours of tick removal, and (3) the local rate of infection of these ticks with *B. burgdorferi* is more than 20 percent. Doxycycline (4 mg/kg/day in two divided doses, up to 100 mg per dose) is indicated in children older than 8 years of age and adults for treatment of erythema migrans, isolated cranial nerve palsy, uncomplicated cardiac disease, and uncomplicated arthritis.[317] Topical tetracyclines have been used extensively for the treatment of acne vulgaris and other dermatologic illnesses.[145]

Adverse Effects

Gastrointestinal disturbances are the most common side effects associated with tetracycline and include anorexia, nausea, emesis, flatulence, and diarrhea. These symptoms occur less frequently with minocycline. Esophageal ulceration has been associated with the oral administration of tetracyclines.[108] All tetracyclines except doxycycline can cause a negative nitrogen balance, with an elevation in blood urea nitrogen that usually is not significant except in the presence of underlying renal insufficiency. Demeclocycline can cause nephrogenic diabetes insipidus and, for this reason, has been used for treatment of the syndrome of inappropriate antidiuretic hormone secretion. Rarely, tetracyclines have been associated with hepatic injury, as manifested by elevated transaminases and diffuse vacuolar fatty metamorphosis on biopsy, with or without pancreatitis. The effect is dose-related, and the risk is increased with pregnancy, malnutrition, and preexisting renal or hepatic disease and

in patients receiving other hepatotoxic agents. The use of tetracyclines in children younger than 9 years of age is relatively contraindicated because tetracyclines chelate with calcium and can be deposited in developing bones and teeth and lead to a transient decrease in bone growth, permanent tooth discoloration, and enamel hypoplasia. The risk that these side effects will occur with one course at an appropriate dosage is low; the degree of tooth discoloration is associated with the total dosage administered.[127] Minocycline has been associated with reversible vestibular toxicity. All tetracyclines have been noted to cause pseudotumor cerebri, a benign elevation in intracranial pressure that is reversible after discontinuation of the drug. Some data suggest that an increased risk may exist with the concurrent use of tetracycline and isotretinoin. Tetracyclines have been associated with an exaggerated sunburn reaction after sun exposure. This risk occurs most frequently with demeclocycline and rarely with minocycline. Hypersensitivity reactions occur infrequently and include morbilliform rash, urticaria, exfoliative dermatitis, and, rarely, anaphylaxis. Hyperpigmentation of the mucosal membranes, skin, and nails has been reported with the use of tetracycline, particularly minocycline.

Drug–drug interactions are numerous. A decrease in absorption of tetracyclines can occur with the coadministration of oral antacids, bismuth subsalicylate, iron, kaolin or pectin, zinc sulfate, and other divalent or trivalent cations that chelate the antibiotic. A reduced effect of tetracyclines because of increased metabolism is associated with the concomitant use of doxycycline with barbiturates, carbamazepine, phenytoin, rifampin, and alcohol in heavy drinkers. Coadministration with tetracyclines can increase the effect of oral anticoagulants, digoxin, lithium, and theophylline and can decrease the effect of oral contraceptive agents and oral iron. Tetracyclines can inhibit the in vitro bactericidal activity of penicillins and aminoglycosides. Other drug–drug interactions include benign intracranial hypertension with the concomitant administration of vitamin A, severe nephrotoxicity with the coadministration of methoxyflurane and tetracycline, and localized hemosiderosis with amitriptyline and minocycline.

Lincosamides

Lincosamide antibiotics consist of an amino acid linked to an amino sugar. Lincomycin, elaborated by *Streptomyces lincolnensis* variety lincolnensis, originally isolated from a soil sample near Lincoln, Nebraska, was the first lincosamide available for use. Clindamycin, a semisynthetic derivative of lincomycin produced by the substitution of a chlorine atom for a hydroxyl group at position 7, was available for use in the early 1970s. Because clindamycin has increased antibacterial activity and better oral absorption than lincomycin, lincomycin rarely is used.

Mechanisms of Action

Lincosamides bind to the 50S subunit of susceptible bacterial ribosomes close to the peptidyl transferase center and thereby inhibit protein synthesis. Data indicate that clindamycin causes dissociation of peptidyl-tRNAs from the ribosome, depletion of free tRNA pools, and prevention of the egress of nascent peptides through a tunnel in the 50S subunit.[298] Because the ribosomal binding sites for lincosamides overlap with those of chloramphenicol and erythromycin, concurrent use of these agents can result in antagonism and should be avoided. Lincosamides usually are bacteriostatic but can be bactericidal against highly susceptible microorganisms in the presence of high lincosamide concentrations.

Mechanisms of Resistance

Some bacteria, including members of the Enterobacteriaceae and *Pseudomonas* and *Acinetobacter* spp., are inherently resistant to lincosamides, most likely because of relative impermeability of the outer membrane of the cell wall. Acquired resistance can develop as a result of altered ribosomal targets and, less commonly, lincosamide inactivation, whereas resistance as a result of reduced lincosamide uptake has not been described. Two mechanisms by which bacteria can alter their ribosomes and acquire lincosamide resistance have been identified. High-level resistance because of an altered protein component of the 50S ribosomal subunit after a one-step chromosomal mutation confers resistance to erythromycin and often to the lincosamides. Plasmid-mediated MLS_B resistance occurs when adenine residues on the 23S RNA component of the 50S ribosomal subunit are methylated, and an altered target is created that confers cross resistance to macrolides, lincosamides, and streptogramin B. The production of ribosomal methylases is encoded by the erm class of genes.[263] This resistance can be constitutive or inducible and can be seen in staphylococci, streptococci, and *Bacteroides* spp. Erythromycin is the most potent inducer of MLS_B resistance in staphylococci, whereas any macrolide, lincosamide, or streptogramin B can be an inducer in streptococci. Some strains of *B. fragilis* can have inducible MLS_B resistance that is not detected easily by disk agar diffusion susceptibility testing[292] but is recognizable because of frequently concurrent high-level erythromycin resistance. A macrolide-spectrogramin-B pattern of resistance that is plasmid-mediated results in macrolide resistance as a result of active ATP-dependent efflux pumps encoded by the *mef(A)* and *msr(A)* genes. Isolates with these resistance genotypes are resistant to 14- and 15-membered ring macrolides and streptogramin B but not to clindamycin.[202] Rarely, staphylococci produce a plasmid-mediated, nonconjugative nucleotidyltransferase that inactivates lincosamides and results in high-level resistance to lincomycin and tolerance to clindamycin (MBC/MIC ratio >32).

In Vitro Activity

Both lincosamides are effective in vitro against gram-positive cocci, whereas clindamycin also is active against a wide range of anaerobic bacteria. Clindamycin is many times more active than lincomycin and is as active as or slightly more active than erythromycin against staphylococci, pneumococci, group A streptococci, and viridans

streptococci. Unlike erythromycin, the lincosamides do not have clinically significant activity against *H. influenzae*, *M. pneumoniae*, or *Neisseria* spp. Clindamycin is active against many gram-positive cocci, including penicillinase-producing and non–penicillinase-producing staphylococci and groups A, B, C, and G β-hemolytic streptococci and pneumococci, but it is not active against enterococci or most health care–associated methicillin-resistant staphylococci. Rates of in vitro inducible erm-mediated MLS_B resistance among CAMRSA isolates vary widely, ranging from 4.5 percent in Houston[166] to 94 percent in Chicago.[110] Presence of this type of resistance can be detected in erythromycin-resistant strains of *S. aureus* with the use of the double-disk diffusion assay (D-test), in which clindamycin- and erythromycin-impregnated disks are placed 15 to 20 mm apart on Müeller-Hinton agar that has been inoculated with a standardized (0.5 McFarland) suspension of *S. aureus.* The finding of a D-shaped blunting of the circular zone of inhibition around the clindamycin disk on the side closest to the erythromycin disk indicates the presence of in vitro–inducible MLS_B resistance. These isolates have a high rate of mutation to constitutive clindamycin resistance, a trait that would confer a selective advantage during clindamycin therapy. The use of clindamycin for D-test–positive *S. aureus* infections has been reported to result in treatment failure in a few patients. Therefore, alternative effective antimicrobial agents should be sought, or, if empirical clindamycin therapy has been initiated, response to therapy should be carefully monitored.[123,202] Erythromycin and lincosamide resistance in pneumococci and group A streptococci has been increasing. Surveillance studies revealed rates of clindamycin resistance among multidrug-resistant pneumococci to range from 12 to 19 percent in the United States and Europe, respectively.[156] Most facultative aerobic gram-negative bacilli, with the exception of *Campylobacter* spp. (including *C. jejuni* and *C. fetus*) and *H. pylori*, are inherently resistant to clindamycin. Anaerobes frequently susceptible to clindamycin include the anaerobic gram-negative bacilli *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp.; the non–spore-forming gram-positive bacilli *Propionibacterium*, *Eubacterium*, and *Actinomyces;* the anaerobic gram-positive cocci *Peptococcus*, *Peptostreptococcus*, and microaerophilic streptococci and many *Clostridium* organisms, excluding *C. difficile*, *Clostridium sporogenes*, and *Clostridium tertium*. Clindamycin resistance does occur, especially in *Fusobacterium varium*, the nonfragilis *Bacteroides* group, an increasing proportion of *B. fragilis* isolates (≤≈30% in some series),[5] and as many as 20 percent of anaerobic gram-positive cocci. When combined with other agents, clindamycin is active against certain other pathogens such as *Babesia*, *Plasmodium*, *Pneumocystis jiroveci*, and *T. gondii.*

Pharmacokinetics

Oral absorption of lincosamides occurs rapidly. The presence of food delays but does not decrease the absorption of clindamycin, but it does reduce the absorption of lincomycin. Concomitant administration of kaolin or attapulgite-containing antidiarrheal agents can decrease absorption; therefore, these agents should not be administered within 2 hours before or 3 to 4 hours after oral lincosamides are given. Lincosamides are distributed rapidly and widely to most tissues and fluids, including saliva, sputum, respiratory tissue, pleural fluid, soft tissues, bones and joints, brain, prostate, semen, appendix, and peritoneal fluid.[224,240] Lincosamides are transported actively into macrophages and polymorphonuclear leukocytes, and high concentrations are achieved in bile, urine, and bone. Penetration into CSF is limited, unless inflammation is present. In experimental pneumococcal meningitis, concentrations of clindamycin in CSF were approximately 10 percent of the corresponding serum values. Lincosamides are highly protein-bound, with values ranging from 70 to 75 percent for lincomycin and 92 to 94 percent for clindamycin. The inactive palmitate and phosphate esters are hydrolyzed in the liver to clindamycin, the active agent. Clindamycin undergoes hepatic biotransformation to active and inactive metabolites. Ten percent of absorbed lincomycin is excreted unchanged in urine, 3 percent is excreted unchanged in feces, and the remainder is excreted as inactive metabolites, primarily in the biliary system. Elimination is delayed in the presence of severe hepatic insufficiency alone or severe concurrent renal and hepatic impairment, and, therefore, adjustments in dosages may need to be made. Formulations of lincosamides available for use include lincomycin hydrochloride solution for parenteral use. Clindamycin phosphate, a water-soluble ester of clindamycin and phosphoric acid, is available for parenteral use. Oral formulations include clindamycin palmitate hydrochloride granules reconstituted to 75 mg base/5 mL and clindamycin hydrochloride capsules in 75-, 150-, and 300-mg of the base compound. Clindamycin also is available as a topical solution, gel, lotion, foam, pad, and vaginal cream and suppository.

Indications for Use

Lincomycin can be used for the treatment of serious infections caused by susceptible strains of staphylococci, pneumococci, other streptococci, or anaerobic organisms, but it rarely is used in pediatric patients. Clindamycin is effective against and has been approved for treatment of susceptible strains of staphylococcal bone and joint infections[102]; anaerobic pelvic infections, including pelvic inflammatory disease, nongonococcal tuboovarian abscess, and postsurgical vaginal cuff infections; anaerobic intra-abdominal infections, including peritonitis and abscesses; pneumonitis, empyema, and lung abscesses caused by anaerobes and as a second-line agent for infections caused by susceptible strains of pneumococci and staphylococci; anaerobic septicemia; and skin and soft tissue infections caused by anaerobes, susceptible strains of staphylococci, and streptococci. Clinical prediction rules relating to resistance among community-acquired, community-onset health care–associated and traditional nosocomial staphylococcal isolates are becoming less reliable because certain strains with distinctive genetic determinants of virulence (e.g., *pvl* genes) and antibiotic resistance (e.g., SSCmec) are tending to predominate.[144,217] Prevalences of constitutive and inducible

MLS_B resistance in community-associated *S. aureus* infections generally are increasing in the United States, although rates vary geographically and temporally as a function of predominant circulating clones.[67] Based on current experience, clindamycin should not be used for empirical therapy of suspected *S. aureus* infections if the local clindamycin resistance rate exceeds 10 to 15 percent. Conversely, clindamycin is effective in treating serious infections caused by clindamycin-susceptible (D-test–negative) CAMRSA infections, including bacteremia, osteomyelitis, suppurative arthritis, pleural empyema, and skin and soft tissue infections.[164,202] Clindamycin also is effective and has been approved as a topical agent for acne vulgaris. Unconfirmed retrospective data suggest that clindamycin in combination with a β-lactam antibiotic, with surgery if indicated, may be the most effective treatment of invasive *S. pyogenes* infections.[322] Other infections for which clindamycin may be effective but has not been approved for therapy include acute otitis media caused by penicillin-resistant pneumococci that has failed to respond to other antibacterial agents,[10] chronic suppurative otitis media or chronic sinusitis in which anaerobes may play a role, chronic pharyngeal carriers of group A streptococci,[293] odontogenic infections, toxoplasmosis of the CNS (in combination with pyrimethamine), uncomplicated *falciparum* malaria[179] or babesiosis (in combination with quinine), and mild-to-moderate *P. jiroveci* pneumonia in patients with acquired immunodeficiency syndrome (AIDS) (in combination with primaquine).[32] Because of poor penetration into CSF, this drug is not approved for the treatment of meningitis. Clindamycin is a third-line agent for endocarditis prophylaxis for upper respiratory tract, dental, or oral procedures in persons allergic to or intolerant of amoxicillin and erythromycin. Oral and intravenous formulations of clindamycin are approved for use in infants and children of all ages. The bitter taste of the oral suspension may limit compliance.

Adverse Effects

The most frequent side effects include generalized morbilliform-like rash and mild, self-limited diarrhea occurring in as many as 10 percent and in 2 to 20 percent of patients, respectively. Other gastrointestinal disturbances include anorexia, nausea, vomiting, flatulence, abdominal pain, and a metallic taste. Pseudomembranous colitis, a serious and sometimes fatal illness, is the adverse event posing the most concern. Most antibiotics have been associated with pseudomembranous colitis, but those most frequently implicated include ampicillin, lincosamides, and cephalosporins. The incidence of lincosamide-associated pseudomembranous colitis varies from 0.1 to 10 percent. Antibiotic-associated pseudomembranous colitis is caused by overgrowth of toxin-producing strains of *C. difficile;* at least two extracellular toxins are elaborated: toxin A, a potent enterotoxin; and toxin B, a cytotoxin.[52] The risk for developing disease is increased in elderly patients and those with chronic, debilitating conditions. Pseudomembranous colitis is unrelated to the total antibiotic dosage, duration of therapy, route of administration, or underlying disease. The onset most frequently occurs between days 4 and 9 of therapy, but signs and symptoms develop in one third of patients 2 to 10 weeks after discontinuation of the antibiotic. More than 80 percent of patients have fever, leukocytosis, crampy abdominal pain, and watery diarrhea, and 5 to 10 percent have bloody diarrhea. Sigmoidoscopic findings include plaquelike lesions on colonic or rectal mucosa consisting of polymorphonuclear leukocytes, chronic inflammatory cells, fibrin, and epithelial debris. Treatment includes prompt discontinuation of the antibiotic, avoidance of antiperistaltic agents, and oral administration of metronidazole. However, several factors that limit the effectiveness of metronidazole include occasional resistance of *C. difficile*, absence of convenient oral preparations for children, and complete absorption of the drug in the upper gastrointestinal tract so that bactericidal levels are achieved erratically in the lower gastrointestinal tract. Although this indication in children has not been approved by the FDA, metronidazole is considered the drug of choice. Use of a nonabsorbable oral vancomycin formulation is potentially effective. However, because of its expense, bad taste, associated relapse rate of 20 percent, and potential to induce resistance in enterococci, vancomycin should be reserved for children who fail to respond to metronidazole therapy. Potential alternative therapies for multiple recurrences of pseudomembranous colitis include probiotics, certain strains of yeast, solution of fresh stool from healthy donors, or cholestyramine.[52] An approved agent for traveler's diarrhea, rifaximin, has been shown to be effective in a few patients with recurrent or persistent *C. difficile* infection.

Other less common adverse events include hypersensitivity reactions such as urticarial rash, drug fever, and eosinophilia; transient neutropenia, agranulocytosis, or thrombocytopenia; and a mild, reversible elevation in hepatic transaminases. Caution must be exercised when administering lincosamides to newborns; fatal gasping syndromes have been described that possibly are related to the preservative benzyl alcohol.

Drug interactions include incompatibility with many agents in solution, including ampicillin, barbiturates, calcium gluconate, phenytoin, and magnesium sulfate, as well as interaction with hydrocarbon-containing inhalational anesthetics. Lincosamides are weak neuromuscular blockers,[285] but they can enhance neuromuscular blockade when they are administered concurrently with neuromuscular blockers. Chloramphenicol and macrolides can have an antagonistic effect when they are administered concurrently with lincosamides because of competition for ribosomal binding sites.

Linezolid

Linezolid is the first of a new class of oxazolidinone antibiotics that was approved for use in children by the FDA in 2002. Linezolid is a totally synthetic compound with favorable activity against multidrug-resistant, gram-positive bacteria.[92]

Mechanisms of Action

Linezolid inhibits an early stage of ribosomal protein synthesis by binding to a unique site, domain V on the bacterial 23S ribosomal RNA of the 50S subunit, and prevents formation of a functional 70S initiation complex. Inhibition of this process interferes with the bacterial translation process. Furthermore, linezolid causes ribosomes to shift reading frames and to read through stop codons, thereby affecting translational fidelity.[302]

Mechanisms of Resistance

Rarely, mutations conferring resistance have been reported in the peptidyl transferase region of the 23S rRNA genes. Cross resistance between linezolid and chloramphenicol is caused by a single nucleotide mutation in the peptidyl transferase center.[302] Cross resistance between linezolid and other classes of antibiotics that target the ribosome, such as aminoglycosides, macrolides, lincosamides, and streptogramins, rarely occurs because these agents target a distinct mechanism of protein elongation. Resistance to linezolid has been reported in as many as 4 percent of clinical isolates of enterococci, particularly *E. faecium*, *S. aureus*, and coagulase-negative staphylococci.[96] Predisposing factors include indwelling devices, undrained abscesses, and prolonged administration of linezolid, particularly if subtherapeutic antibiotic concentrations are achieved.[264]

In Vitro Activity

Time-kill studies demonstrated that linezolid is bacteriostatic against enterococci and staphylococci and bactericidal against most strains of streptococci. Linezolid is active against MRSA, coagulase-negative staphylococci, and vancomycin-resistant enterococci. Furthermore, linezolid has broad activity against *Nocardia* and rapidly growing mycobacteria, as well as slowly growing tuberculous and nontuberculous mycobacteria.[53]

Pharmacokinetics

Dosage adjustment is not necessary when switching from intravenous to oral formulations because the oral bioavailability is approximately 100 percent. Absorption is not significantly affected by food. The antibiotic is distributed to well-perfused tissues and has a relatively low protein binding (31%) that contributes to the high degree of penetration into bone, muscle, fat, alveolar cells, lung extracellular lining fluid, and CSF. Linezolid is metabolized primarily by oxidation and has no interaction with the CYP450 enzymes. The elimination half-life in children is less than 5 hours and is shorter than in adults. The disposition of linezolid varies as a function of age, with faster clearance and greater volume of distribution in children younger than 11 years of age. The AUC values for children are lower than those for adults, whereas preterm neonates (gestational age <34 weeks) within the first week of life have larger AUC values than many full-term neonates and older children. The pharmacokinetics of linezolid in adolescents 12 years of age and older is not significantly different from that of adults. Dosage adjustment is not necessary for patients with renal insufficiency or mild-to-moderate hepatic insufficiency.[162]

Indications for Use

The safety and effectiveness of linezolid have been established for pediatric patients from birth through 17 years of age. Intravenous and oral linezolid is indicated for treatment of children with (1) uncomplicated and complicated skin and skin structure infections caused by oxacillin-susceptible or oxacillin-resistant *S. aureus*, or by group A or group B β-hemolytic streptococci; (2) community- and health care–associated pneumonia caused by penicillin-susceptible strains of *S. pneumoniae* or oxacillin-susceptible or oxacillin-resistant *S. aureus;* and (3) infections caused by vancomycin-resistant enterococci.[165] The recommended dosage for newborns (≥34 weeks' postconceptual age) and children up to the age of 11 years is 10 mg/kg intravenously or orally every 8 hours for 10 to 14 days for pneumonia and complicated skin and skin structure infections and for 14 to 28 days for pneumonia or bacteremia caused by vancomycin-resistant enterococci. The 10-mg/kg dose is administered every 12 hours for 5- to 11-year-old children with uncomplicated skin and soft tissue infections and for premature neonates (gestational age <34 weeks) within the first week of life. The dose for adolescents older than 11 years and adults is 600 mg every 12 hours, with a 1200-mg daily limit. Linezolid offers a safe therapeutic alternative to vancomycin for multidrug-resistant, gram-positive bacteria and has the additional advantage of being available in an oral liquid preparation (100 mg/5 mL), which facilitates sequential intravenous and oral therapy.[91,153,162,165] Safety and efficacy of therapy for longer than 28 days have not been evaluated in controlled clinical trials. Currently, no indication exists for treatment of mycobacterial infections, although linezolid has been used successfully for certain nontuberculous infections.

Adverse Effects

Data from multiple trials indicate that linezolid is safe and well tolerated, with adverse events similar to those of comparative drugs. The most common drug-related adverse events are diarrhea, nausea, vomiting, rash, and headache.[272] However, dose and duration-dependent reversible myelosuppression, including mild-to-moderate anemia and thrombocytopenia and rarely neutropenia, have been reported in children treated with linezolid.[209,272] Therefore, weekly monitoring of complete blood counts is recommended in patients who receive linezolid for longer than 2 weeks, have preexisting myelosuppression, or receive other myelosuppressive antibiotics. Other rare adverse effects that warrant prompt evaluation include peripheral and optic neuropathy, lactic acidosis, and the serotonin syndrome in patients receiving concomitant selective serotonin reuptake inhibitors. The oral suspension formulation contains

phenylalanine, which is contraindicated in children with phenylketonuria.

Rifamycins

The rifamycins are a group of complex macrocyclic antibiotics that were isolated from *Streptomyces mediterranei* in the early 1960s. Rifampin (rifampicin) and rifabutin are structurally related, semisynthetic broad-spectrum antibiotics derived from rifamycin B and S, respectively. These agents avidly bind to the subunit of the DNA-dependent RNA polymerase, prevent attachment of the enzyme to DNA, and thus block initiation of RNA transcription and protein synthesis. Rifabutin was approved in 1992 for prevention of disseminated MAC disease in adults with advanced HIV infection. Single-point mutations that determine resistance develop rapidly when rifamycins are used alone. Therefore, these antibiotics should be administered in combination with other antimicrobial agents when indicated. Rifaximin also is a semisynthetic derivative of rifamycin that was approved by the FDA in 2004 for the treatment of individuals 12 years of age or older who have nondysenteric and afebrile traveler's diarrhea caused by noninvasive strains of *E. coli*.[4]

In Vitro Activity

Rifampin usually is bactericidal, but it may be bacteriostatic, depending on the organism and drug concentration. Rifamycins have excellent in vitro activity against many gram-positive cocci, including many methicillin-resistant staphylococci and penicillin-nonsusceptible *S. pneumoniae* (enterococci are notable exceptions); some gram-negative organisms, including meningococci, gonococci, and *H. influenzae; Legionella; C. trachomatis; T. gondii; M. tuberculosis;* and *M. leprae*. Rifampin is active against *Mycobacterium kansasii*, but not against most other species of atypical mycobacteria. In contrast, rifabutin is active against most atypical mycobacteria, except *M. chelonae*. Rifabutin also is more active than rifampin against rifampin-susceptible strains of *Mycobacterium tuberculosis* and is active against approximately one third of rifampin-resistant strains.[193,215] Resistance to rifampin is mediated by point mutations in the *rpoB* gene that encodes the subunit of the DNA-dependent RNA polymerase, as well as alterations in membrane permeability. Surveillance data documented that 3 percent of meningococcal isolates in the United States are resistant to rifampin.[167] Rifaximin has activity against most enteric bacterial pathogens, including *C. difficile*, *C. jejuni*, *E. coli*, *H. pylori*, *Salmonella* spp., *Shigella* spp., *V. cholera*, and *Yersinia enterocolitica*.[4]

Pharmacokinetics

Rifampin and rifabutin are highly lipid-soluble and highly protein-bound (72% to 89%) molecules. Consequently, they are well absorbed from the gastrointestinal tract and have excellent intracellular penetration. The drugs reach therapeutic concentrations in the CSF (≈10% to 20% of simultaneous serum concentrations), particularly in the presence of inflammation of the meninges. They are metabolized primarily by the liver through deacetylation, and 30 to 40 percent of the drug is excreted by the biliary system. In the presence of hepatic dysfunction, dosage adjustments are necessary, whereas no alteration in dosage is required for children with renal dysfunction. In adults, rifabutin has a significantly longer mean terminal half-life than rifampin (45 vs. 2 to 5 hours).[256] Rifampin, however, has a very long postantibiotic effect. Rifaximin is poorly absorbed, with a bioavailability of less than 0.4 percent. Therefore, dosage adjustment of rifaximin for hepatic or renal dysfunction is not necessary and the agent is unlikely to interact with medications metabolized by the CYP450 system.

Indications for Use

The only situation in which rifampin should be considered for use as a single antibacterial agent is for prophylaxis of infection, because resistance to rifampin can develop rapidly when this agent is used alone for therapeutic purposes. Prophylaxis with rifampin monotherapy is indicated to eradicate nasopharyngeal colonization in close contacts of individuals with infections caused by *H. influenzae* type b[125,219] and *N. meningitidis*,[30] as well as index cases with these infections, unless they were treated with third-generation cephalosporins.

The use of rifampin, combined with two or three other bactericidal antituberculosis agents for the treatment of active tuberculosis, as well as its combined use with clofazimine and dapsone for the treatment of leprosy, is considered an essential component of effective regimens. The effect of adding rifampin to certain antibiotics for treatment of other infections often is unpredictable and may result in synergistic, additive, indifferent, or antagonistic activity. In some patients, rifampin can be considered part of a combination regimen for the treatment of (1) meningitis caused by penicillin- and cephalosporin-resistant *S. pneumoniae* in combination with a third-generation cephalosporin and vancomycin; (2) shunt- or catheter-associated staphylococcal infections, often with removal of the foreign material; (3) *S. aureus* implant-related orthopedic infections in combination with an effective agent; (4) non–life-threatening susceptible MRSA skin and skin structure infections in combination with TMP-SMX with the theoretical benefit of eradicating MRSA carriage, considering that rifampin achieves high concentrations on mucosal surfaces; (5) prosthetic valve endocarditis caused by staphylococci; (6) complicated or severe *B. henselae* infection (cat-scratch disease); (7) brucellosis in combination with TMP-SMX, a tetracycline, or an aminoglycoside[197]; (8) MAC-associated disseminated disease or lymphadenitis, if not completely resectable, in combination with ethambutol and azithromycin or clarithromycin; (9) *L. pneumophila* pneumonia in combination with a macrolide if response to macrolides alone is poor; and (10) multidrug-resistant *S. maltophilia* in combination with colistin (i.e., colistimethate sodium or polymyxin E) based on favorable in vitro data.[167,193] Furthermore, rifampin and minocycline-impregnated central venous catheters have been used successfully in adults to prevent catheter colonization and bloodstream infection with gram-positive

and gram-negative pathogens, as well as with *Candida* spp. The American Academy of Pediatrics recommends selective use of these catheters in infants weighing more than 3 kg and children if the local catheter-related bloodstream infection rate exceeds 3.3/1000 catheter days and if the standard protective procedures already have been implemented.[85,237] In the last circumstance, surveillance for resistance is important. Many physicians use rifampin combined with antistaphylococcal agents for treatment of disseminated MRSA infection without evidence from controlled studies of its effectiveness.

Rifabutin is effective for the treatment of most mycobacterial species, *H. pylori*, and *T. gondii* in adults. Limited data are available for the treatment of MAC infections in children with HIV infection. Clinical studies in adults with advanced HIV infection indicate that administration of daily clarithromycin or weekly azithromycin is superior to rifabutin alone for prophylaxis of MAC infection.[215] The safety and efficacy of rifabutin for prophylaxis of MAC infection in children have not been established.[163]

Rifampin is available in capsule (150 and 300 mg) and intravenous formulations. Rifabutin is available only in capsule (150 mg) form. A suspension can be compounded by the pharmacy, or the capsule contents can be mixed with thick, sweet food for infants and young children. Absorption of rifampin is optimal if administered 1 hour before or 2 hours after a meal, whereas a high-fat meal decreases the rate, but not the total amount, of absorption of rifabutin. The use of fixed-dose combinations of rifampin, isoniazid, and pyrazinamide is not recommended for children. Although the safety and efficacy of rifapentine, a rifamycin antibiotic similar in structure and activity to rifampin and rifabutin, have not been established for children younger than 12 years of age, a pharmacokinetic study indicated that dosages in children need to be greater than those for adults to achieve comparable systemic exposure.[33] Combination treatment with rifapentine and isoniazid given once weekly for 3 months for the treatment of latent tuberculosis infection has recently been proposed for patients older than 12 years of age, with results similar to those of a 9-month regimen of daily isoniazid for the same indication.[290] The approved dosage of rifaximin for the treatment of traveler's diarrhea in adolescents and adults is 200 mg three times per day for 3 days. A dosage of 400 mg twice per day for 3 days apparently is equally effective and may be better tolerated by patients. Rifaximin should not be used to treat systemic infections or mucosally invasive enteric infections. Rifaximin is not indicated currently for the treatment of dysenteric diarrhea secondary to *Shigella*, *Salmonella*, or *Campylobacter* spp. infection or for the treatment of complicated diarrhea with fever, systemic toxicity, or bloody stools. The role of this agent for prophylaxis of traveler's diarrhea is being studied.[4,14]

Adverse Effects

Adverse events associated with rifampin include gastrointestinal disorders, rash, hepatotoxicity, hypersensitivity, and a flulike syndrome. Adverse reactions to rifabutin include gastrointestinal disorders, rash, leukopenia, neutropenia, and, rarely, uveitis, although safety data in children are limited. The parenteral form of rifampin is associated with thrombophlebitis. Routine determination of serum aminotransferase concentrations is not recommended for children receiving brief or prolonged courses of therapy, except for those with clinical evidence of hepatitis or severe or disseminated tuberculosis. In these situations, at least monthly measurements should be performed. In addition, patients should be warned that rifamycins discolor urine, tears, sweat, and feces and permanently stain soft contact lenses. Because rifamycins induce hepatic CYP450 enzyme activity, they may interact with other medications administered concurrently and cause decreased concentrations of some antiretroviral agents, particularly protease inhibitors, azole antifungal agents, barbiturates, oral contraceptives, clarithromycin, cyclosporine, digoxin, sulfonylureas, thyroxine, and warfarin (Coumadin). Conversely, rifamycin serum drug concentrations may increase if it is administered with other drugs that inhibit hepatic enzymes, and the dose of rifamycin antibiotic may need to be reduced by as much as 50 percent. Rifabutin induces hepatic enzymes to a lesser extent than does rifampin and therefore has less potential for drug interactions.[193,215] Rifaximin is well tolerated and has an excellent safety profile.

Antibiotics Interfering with Protein Synthesis Not Approved for Use in Children

Fidaxomicin is a macrocylic antibody isolated from the fermentation broth of *Dactylosporangium aurantiacum* that inhibits the bacterial sigma subunit involved in protein synthesis. It has a narrow spectrum of activity with bactericidal effect against gram-positive anaerobes, including *C. difficile*, and demonstrating activity for the NAP1/BI/027 strain. It received FDA approval in 2011 for treatment of *C. difficile*–associated diarrhea in adults. Fidaxomicin was shown to be noninferior to vancomycin for the treatment of *C. difficile* infection and was effective in preventing recurrences. It has minimal systemic absorption and appears to be well tolerated.[81,103,315]

AGENTS THAT TARGET NUCLEIC ACID

Fluoroquinolones

Fluoroquinolone antibiotics are derivatives of nalidixic acid. In contrast to nalidixic acid, fluoroquinolones have (1) a broader spectrum of activity that includes aerobic gram-negative enteric organisms, particularly Enterobacteriaceae, *Haemophilus* spp., *Neisseria* spp., *M. catarrhalis*, nonenteric gram-negative bacilli such as *P. aeruginosa*, oxacillin-susceptible staphylococci, some streptococci, bacteria associated with atypical pneumonia, certain genital pathogens, and certain strains of mycobacteria; (2) better penetration into tissues; (3) good intracellular penetration; and (4) rapid bactericidal activity.

Mechanisms of Action

Fluoroquinolones are the only class of antibacterial agents in clinical use that directly inhibit DNA synthesis. They bind to bacterial DNA gyrase and topoisomerase IV. Inhibition of bacterial gyrase causes relaxation of the supercoiled DNA that leads to termination of chromosomal replication and interference with cell division and gene expression. Inhibition of the activity of topoisomerase IV leads to separation of two united DNA molecules and subsequent interference with cellular replication.

Mechanisms of Resistance

A growing concern is that widespread use of fluoroquinolones among adult populations has been associated with resistance rates, especially among Enterobacteriaceae, that exceed 50 percent in some regions. Mechanisms of resistance include chromosomal mutations in genes that encode fluoroquinolone target enzymes (i.e., DNA gyrase and topoisomerase IV), efflux pumps, or porin (i.e., outer-membrane diffusion) channels. Newly identified plasmid-mediated resistance determinants in strains of *K. pneumoniae*, *E. coli*, *Enterobacter*, and other enteric bacteria include (1) Qnr, a protein that protects DNA gyrase from quinolone action and is associated with multidrug resistance and (2) a variant of the aminoglycoside acetyltransferase found in gram-negative bacteria that is capable of inactivating ciprofloxacin.[189,265] Fluoroquinolone-resistant strains of *N. gonorrhoeae* are common findings in many parts of the world and are spreading in the United States, especially in California and Hawaii. The CDC no longer recommends fluoroquinolones for treatment of gonorrhea in the United States.[316] Other bacteria with increasing rates of resistance include *S. pneumoniae* (≈3% to ciprofloxacin with a breakpoint 4 μg/mL or greater vs. no resistance to levofloxacin as of 2004 among invasive pediatric isolates in the United States[101]) and intestinal pathogens such as *Campylobacter jejuni*, *Shigella* spp., *Salmonella* spp., certain strains of *Klebsiella pneumoniae*, *E. coli*, *P. aeruginosa*, among others.[8]

In Vitro Activity

Levofloxacin and moxifloxacin have greater potency than ciprofloxacin against gram-positive cocci, and moxifloxacin has enhanced activity against anaerobic bacteria, although in some series, approximately 50 percent of invasive *Bacteroides* spp. are resistant to moxifloxacin.[121] Ciprofloxacin remains the most potent marketed fluoroquinolone against gram-negative bacteria, particularly against some strains of *P. aeruginosa*, *Providencia* spp., *Proteus* spp., and *S. marcescens*. In vitro studies of newer and investigational fluoroquinolones against penicillin and cephalosporin-resistant pneumococci indicate excellent activity, whereas activity of ciprofloxacin, norfloxacin, and ofloxacin is limited. Fluoroquinolone use for MRSA and oxacillin-resistant, coagulase-negative staphylococci is limited because resistant mutants can be selected relatively easily, thus leading to treatment failure and relapse. Constitutive high-level resistance exists among MRSA isolates from patients with CAMRSA infections in some areas of the United States. Although MICs tend to be lower for newer (e.g., moxifloxacin and gatifloxacin) in contrast to older (e.g., ciprofloxacin and levofloxacin) fluoroquinolones, genes conferring fluoroquinolone resistance in *S. aureus* confer resistance to the entire class of agents.[123] Activity against enterococci is marginal or absent. Fluoroquinolones are effective against atypical pneumonia pathogens (i.e., *Chlamydophila pneumoniae*, *L. pneumophila*, and *M. pneumoniae*) and certain genital pathogens (i.e., *C. trachomatis*, *U. urealyticum*, and *Mycoplasma hominis*). Ciprofloxacin, levofloxacin, and moxifloxacin are active in vitro against certain strains of *M. tuberculosis*, *Mycobacterium fortuitum*, *M. kansasii*, and *M. chelonae* and are less active against MAC. No quinolone antibiotic has been shown to be active against *T. pallidum*.

Pharmacokinetics

The fluoroquinolones generally have excellent bioavailability that is not substantially affected by food, with values of 70 percent for ciprofloxacin, 85 percent for moxifloxacin, and greater than 95 percent for ofloxacin and levofloxacin. These drugs have large volumes of distribution, and they concentrate in the kidneys and in urine (except moxifloxacin, which undergoes hepatic metabolism and biliary excretion). This class of agents has favorable pharmacokinetic properties in children, and their efficacy correlates best with the 24hour AUC/MIC ratio because of a combination of concentration-dependent killing and postantibiotic effect. These properties suggest that large doses given at relatively infrequent intervals would be most effective.[277] However, based on pharmacokinetic studies, doses for patients with cystic fibrosis should be higher and more frequent than for patients without cystic fibrosis, and the dosage should be decreased in proportion to increasing body weight. Fluoroquinolones can interact with a variety of other drugs, including caffeine, cyclosporine, dideoxyinosine, nonsteroidal antiinflammatory drugs, theophylline, and other agents that prolong the QT interval. Coadministration with antacids, ferrous sulfate, and multivitamins containing zinc can reduce oral bioavailability.

Indications for Use

Fluoroquinolones have been used extensively in adults for the treatment of skin and soft tissue, skeletal, and intra-abdominal infections, as well as infections of the urinogenital, gastrointestinal, and respiratory tracts. Fluoroquinolones commonly used in adults include the second-generation agents ciprofloxacin and levofloxacin and the fourth-generation agent moxifloxacin. Other agents with limited indications include enoxacin, ofloxacin, lomefloxacin, norfloxacin (second generation), and gemifloxacin (third generation). Four agents have been withdrawn from the market in the United States: gatifloxacin, grepafloxacin (causes cardiac toxicity), sparfloxacin, and trovafloxacin (causes hepatotoxicity). Ciprofloxacin, levofloxacin, and moxifloxacin are FDA approved

for the treatment of uncomplicated skin infections caused by susceptible organisms in adults. However, none of the fluoroquinolones are FDA approved for treatment of MRSA infections.

Use in pediatric patients has been limited because of the potential for inducing cartilage damage that leads to arthropathy, as demonstrated in juvenile animal studies. However, no convincing evidence exists that quinolone-induced arthropathy occurs in humans. Reversible arthralgia and tendinopathy have a temporal association with fluoroquinolone use. Fluoroquinolones are not approved for use in children and adolescents younger than 18 years, except in the following situations: (1) complicated urinary tract infections and pyelonephritis attributable to *E. coli* in children 1 year of age and older (approved by the FDA in 2004) and (2) exposure to aerosolized *B. anthracis* to prevent onset or progression of disease. However, these drugs have been used in certain clinical settings, such as cystic fibrosis, primarily because they are the only oral antibiotics with activity against *P. aeruginosa*. Furthermore, ciprofloxacin and levofloxacin are available in suspension formulations. In 2002 alone, approximately 500,000 prescriptions for fluoroquinolones were written in the United States for individuals younger than 18 years old.[8] These agents, particularly ciprofloxacin, have been used to treat exacerbations of chronic pseudomonal pulmonary infections in patients with cystic fibrosis; complicated urinary tract infections caused by multidrug-resistant bacteria; chronic suppurative otitis media associated with *P. aeruginosa;* osteochondritis attributable to *P. aeruginosa;* shigellosis, *C. jejuni,* and other bacterial causes of enteritis; multidrug-resistant typhoid fever; cholera; infections in neutropenic patients with cancer; in combination with other agents to treat multidrug-resistant mycobacterial disease; and multidrug-resistant gram-negative bacillary septicemia or meningitis (no controlled trials in children with meningitis have been reported using currently licensed agents).[8,60,271,278] Fluoroquinolones also effectively eradicate nasopharyngeal carriage of susceptible meningococci. One study showed that children with acute otitis media and otorrhea through tympanostomy tubes had better clinical outcomes with fewer adverse effects when they were treated with ciprofloxacin-dexamethasone otic suspension in contrast high-dose amoxicillin-clavulanic acid suspension.[95] Although gatifloxacin is not approved for use in children and currently is not available in the United States, noncontrolled studies confirmed that it is safe and effective for treatment of recurrent acute otitis media and acute otitis media when therapy with standard antimicrobials has failed.[247]

The current recommendation is that parenteral and oral fluoroquinolones should be reserved for situations in which no effective, safe, and nonrestricted alternative antimicrobial agents are available to treat complicated or multidrug-resistant bacterial infections. Appropriate uses should be limited to the following clinical situations: exposure to aerosolized *B. anthracis;* urinary tract infections caused by *P. aeruginosa* or other multidrug-resistant, gram-negative bacteria; chronic suppurative otitis media or malignant otitis externa caused by *P. aeruginosa;* acute or chronic osteomyelitis or osteochondritis caused by *P. aeruginosa;* exacerbations of pulmonary disease in patients with cystic fibrosis who have *P. aeruginosa* colonization and for whom oral therapy is appropriate; susceptible mycobacterial infections as part of a combination regimen; gram-negative bacterial infections in immunocompromised hosts in whom oral therapy is appropriate or resistance to alternative agents is present; gastrointestinal infections caused by multidrug-resistant *Shigella* spp., *Salmonella* spp., *V. cholera*, or *C. jejuni;* and proved bacterial septicemia or meningitis caused by multidrug-resistant pathogens that are susceptible only to fluoroquinolones, that have failed to respond to approved agents, or that require use of a fluoroquinolone because of life-threatening hypersensitivity to alternative agents.[8]

Adverse Effects

Adverse events associated with fluoroquinolone therapy occur in 3 to 17 percent of adult and pediatric patients and cause discontinuation of treatment in 1 to 2 percent. The most common reactions are gastrointestinal, minor CNS disorders, and allergic rashes.[277] Other infrequent adverse reactions include photosensitivity; disorders of glucose homeostasis; prolongation of the QT interval, with rare cases of torsade de pointes, particularly among patients with long QT syndrome; leukopenia; and anaphylactoid reactions. Reversible tendonitis and tendon rupture occur uncommonly in adults.

Sulfonamides

Sulfachrysoidine (Prontosil), discovered in the 1930s, was the first sulfonamide developed. Sulfonamides are broad-spectrum antimicrobial agents derived from sulfanilamide (*p*-aminobenzene sulfonamide) and are structural analogs of *p*-aminobenzoic acid (PABA); they compete with PABA and result in interference with nucleotide synthesis. Sulfanilamide was manipulated to form other compounds with expanded antimicrobial activity and reduced toxicity. Sulfonamides are distributed widely in fluids and tissues. The preparations currently available have greater solubility than earlier compounds and are less likely to cause crystalluria. Sulfonamides available for single-agent use include sulfacytine (Renoquid), sulfadiazine, sulfamethizole (Thiosulfil Forte), SMX (Gantanol), and sulfisoxazole (Gantrisin). Sulfonamide combinations, including TMP-SMX and erythromycin ethylsuccinate-sulfisoxazole acetyl (EES-SSX), are used frequently in pediatrics.

Trimethoprim-Sulfamethoxazole

TMP is a diaminopyrimidine antibiotic available for single-agent use. Combinations of TMP and sulfonamides were used in the late 1960s because of presumed synergistic antibacterial activity, although clinical evidence of synergy is equivocal. Because SMX has rates of absorption and elimination similar to those of TMP, it was the sulfonamide selected for combination. Iclaprim is a novel diaminopyrimidine with a broad spectrum of activity that includes TMP-resistant strains of *S. aureus*

(including MRSA and vancomycin-resistant *S. aureus*), *S. pneumoniae* (including penicillin-nonsusceptible strains), *P. jiroveci*, *Neisseria*, *M. catarrhalis*, and *C. pneumoniae*.[134] Iclaprim inhibits bacterial dihydrofolate reductase; it has been evaluated in clinical trials, including a multicenter, double-blind, phase II, randomized study comparing safety and efficacy with vancomycin but has not been approved by the FDA.[180]

Mechanisms of Action. SMX competitively inhibits dihydropteroate synthetase, the bacterial enzyme that assimilates PABA into dihydrofolic acid; such inhibition results in a reduction in dihydrofolic acid synthesis and therefore a reduction in the amount of tetrahydrofolic acid, a cofactor for nucleotide synthesis.[136] Only bacteria that must synthesize folic acid are potentially susceptible. SMX is bacteriostatic when used alone and can be inhibited by PABA and its derivatives (procaine and tetracaine). TMP reversibly binds and inhibits dihydrofolate reductase, an enzyme that reduces dihydrofolic acid to tetrahydrofolic acid; this activity results in diminished amounts of folic acid, an essential cofactor in nucleic acid production.[56] TMP is bacteriostatic when used alone, but in combination with SMX against susceptible bacteria, bactericidal activity can be achieved by blockade of sequential steps in folic acid metabolism. The effect of sulfonamide on bacteria is circumvented in mammals, which obtain folate from food sources. The reaction inhibited by TMP is similar in bacteria and mammals but differs quantitatively in the extent of binding of the drug to the enzyme; mammalian dihydrofolate reductase is 60,000 times less sensitive to TMP than is the enzyme in susceptible bacteria.

Mechanisms of Resistance. Bacteria can be inherently resistant to either agent or can acquire resistance to TMP, SMX, or both agents. Resistance to SMX and other sulfonamides is associated with hyperproduction of PABA, as demonstrated in strains of *Neisseria* and staphylococci, or is caused by an altered dihydropteroate synthetase enzyme with lower affinity for sulfonamides, as found in *E. coli*, *N. meningitidis*, and *S. pneumoniae*.[300] Chromosomally mediated resistance to TMP on the basis of mutations in the *dhfr* gene has been observed in strains of *S. pneumoniae*, *H. influenzae*, *E. coli*, *Pediococcus*, *B. fragilis*, and *Nocardia* and *Clostridium* spp. Furthermore, *P. aeruginosa*, *K. pneumoniae*, and *S. marcescens* are inherently resistant to TMP because of cell wall impermeability. Acquired resistance to TMP can be plasmid-mediated or chromosomally mediated and occurs in members of the Enterobacteriaceae and in staphylococci and streptococci. Mechanisms of acquired TMP resistance include cell wall impermeability, thymine auxotrophy, resistant dihydrofolate reductase, and overproduction of dihydrofolate reductase, the most common being plasmid-mediated production of dihydrofolate reductases, which are encoded by at least 20 genes. Resistance to sulfonamides is encoded by the dhps family of genes that include the *folP* and *sulI a*nd *sulII* genes. The *sulI* gene usually is linked to other transferable resistance genes, often in the transposons that belong to the Tn21 family. Despite the reduced use of sulfonamides, the genetic determinants for sulfonamide resistance probably persist because of the efficient integron transfer mechanisms.[146] Bacterial resistance to both TMP and SMX can develop as a result of altered cell wall permeability or alternative metabolic pathways (e.g., thymine auxotrophy), whereby they obtain thymine or thymidine from the environment.[300]

In Vitro Activity. TMP-SMX has activity against a broad spectrum of gram-positive cocci and gram-negative enteric pathogens. TMP is more active than the sulfonamide, but the mixture is significantly more effective than either drug alone. Synergism is more likely to occur when the bacteria are susceptible to both drugs, but it can occur even when the bacteria are resistant to only one agent. Bacteria with potential susceptibility to the combination include *Aeromonas hydrophila*, *Brucella*, *B. cepacia*, *Campylobacter*, *E. coli*, *H. influenzae*, *M. catarrhalis*, some environmental mycobacteria, *N. gonorrhoeae*, *Nocardia*, *P. jiroveci*, *Proteus*, *Salmonella*, *S. marcescens*, *Shigella*, oxacillin-susceptible *S. aureus*, *S. maltophilia* (usually with a β-lactam–lactamase inhibitor combination), penicillin-susceptible *S. pneumoniae*, and *Yersinia enterocolitica*. However, high levels of resistance to TMP-SMX among strains of penicillin-nonsusceptible *S. pneumoniae*, methicillin-resistant staphylococci, *M. catarrhalis*, *H. influenzae*, *Neisseria*, *E. coli*, *Klebsiella*, *Salmonella*, *Shigella*, *Campylobacter*, *P. aeruginosa*, *Acinetobacter*, *Nocardia*, *Actinomyces*, *mycobacteria*, *Bacteroides*, *Clostridium*, and *C. pneumonia* limit the usefulness of this antibacterial agent.[146]

Pharmacokinetics. Optimal synergistic activity occurs when a 1:20 ratio of TMP and SMX serum concentrations is attained, as can be achieved after the administration of a fixed 1:5 ratio of TMP to SMX. Both agents are absorbed rapidly and fairly well when administered alone and in combination. Both penetrate most body fluids and tissues, although TMP frequently penetrates extravascular tissues to a greater degree than SMX. Both agents cross the placenta, are excreted in breast milk, and diffuse into pleural, peritoneal, and synovial fluid and CSF. Protein binding varies from 40 to 60 percent for TMP and from 60 to 70 percent for SMX. Both drugs are metabolized in the liver to inactive metabolites. The primary route of elimination is by the kidneys, with small amounts excreted in bile and feces. Dosage adjustments are required for renal impairment.

Available preparations include an oral suspension containing 40 mg of TMP and 200 mg of SMX per 5 mL, tablets containing 80 mg of TMP and 400 mg of SMX, double-strength tablets consisting of 160 mg of TMP and 800 mg of SMX, and a parenteral solution.

Indications for Use. TMP-SMX is approved for the treatment of acute exacerbations of chronic bronchitis in adults, enterocolitis caused by susceptible *Shigella* organisms, acute otitis media caused by susceptible strains of *H. influenzae* or pneumococcus, *P. jiroveci* pneumonia, traveler's diarrhea caused by *Shigella* and enterotoxigenic *E. coli*, and acute or chronic urinary tract infections. Although the combination is not approved for use and not usually prescribed as a first-line antibiotic, TMP-SMX has been effective therapy for typhoid fever, brucellosis,

nocardiosis, sinusitis, biliary tract infections, and bone and joint infections caused by susceptible organisms. Because early studies did not evaluate the effect of prolonged or recurrent therapy on somatic growth or bone marrow function in children, TMP-SMX was not approved for prophylaxis or prolonged treatment of otitis media. It is not recommended for treatment of group A streptococcal tonsillopharyngitis because it does not eradicate the organism or reliably prevent the nonsuppurative sequelae. TMP-SMX is not recommended as first-line monotherapy for community-acquired pneumonia, acute otitis media, or skin infections caused by *S. pyogenes* because of frequent resistance among the etiologic pathogens and absence of efficacy data. TMP-SMX is not FDA approved for the treatment of any form of staphylococcal infection. However, the medical literature contains reports of the successful use of TMP-SMX alone or in combination with one or more agents such as rifampin in the treatment of *S. aureus* infections, including MRSA.[123] TMP-SMX is recommended as an alternative agent to macrolides for treatment of pertussis in individuals 2 months of age or older.[304] TMP-SMX also is an important prophylactic agent that is indicated to prevent bacterial, *P. jiroveci*, and other infections in the following clinical settings: immunosuppressed oncology or posttransplant patients, individuals with HIV who meet clinical and hematologic criteria or certain infants who are exposed in utero to HIV, patients with urinary tract infections who are at risk for recurrent disease, and patients with chronic granulomatous disease or other congenital immunodeficiency syndromes.

Adverse Effects. Most of the side effects occurring during administration of TMP-SMX are caused by the sulfonamide. Gastrointestinal disturbances and hypersensitivity reactions are the adverse events most commonly observed. Anorexia, nausea, vomiting, diarrhea, drug eruption, and photosensitivity reactions can occur in 1 to 4 percent of patients. Hypersensitivity reactions that develop less frequently include erythema nodosum, erythema multiforme (including Stevens-Johnson syndrome), urticaria, anaphylaxis, and thyroid damage. Drug-induced hepatitis has been described but is an unusual event. CNS side effects include vertigo, ataxia, headache, and aseptic meningitis. TMP-SMX can affect renal function when it is administered to persons with underlying renal disease, but the side effect usually is reversible after discontinuation of therapy. Crystalluria occurred more commonly with earlier preparations because of low solubility. SMX has a greater tendency to cause crystalluria than other sulfonamides that are currently available, because of slower absorption and excretion. However, with adequate fluid intake, alkalinization of the urine usually is unnecessary. Interstitial nephritis and tubular necrosis seldom are associated with the use of TMP-SMX. Blood dyscrasias can be a limiting factor to the administration of TMP-SMX. Acute hemolytic anemia has been described after the use of TMP-SMX in patients with glucose-6-phosphate dehydrogenase deficiency. Although they are uncommon in patients with normal hematopoietic systems, aplastic anemia, agranulocytosis, leukopenia, and thrombocytopenia can occur. Prolonged use can result in megaloblastic anemia because of impaired folate usage. Administration of sulfonamide can trigger an acute attack of porphyria. Sulfonamides can displace bilirubin from albumin binding sites. In neonates, especially premature infants, the activity of sulfonamides can be increased as a result of reduced conjugation by the immature liver. Because of the increased risk for development of kernicterus from sulfonamide displacement of bilirubin, the use of sulfonamides during the last month of pregnancy and in the first 2 months of life is discouraged.

Drug–drug interactions with TMP-SMX are numerous. Sulfonamides can displace other drugs from albumin binding sites and thereby result in increased effective activity of the second drug, as can be seen with the concurrent administration of methotrexate, phenytoin, sulfonylurea hypoglycemic agents, thiazide diuretics, and warfarin. Drugs that, when coadministered, can displace sulfonamides from binding sites and lead to increased effective sulfonamide activity include indomethacin, probenecid, and salicylates. Agents that reduce the effect of sulfonamides include methenamine, which results in insoluble urinary precipitates of the sulfonamide, and derivatives of PABA. Sulfonamides are physically incompatible with many drugs, among them aminoglycosides, chloramphenicol, insulin, lincomycin, methicillin, tetracycline, and vancomycin.

Erythromycin Ethylsuccinate–Sulfisoxazole Acetyl

The combination of EES and SSX in a fixed ratio expands the spectrum of antibacterial activity. The mechanism of action, mechanisms of resistance, pharmacokinetics, and adverse events for EESSSX are the same as those for each individual drug. Because EESSSX is effective in vitro against common pathogens causing otitis media in children, it was approved for the treatment of acute otitis media.[42] However, it is not effective against many strains of pneumococci and no longer is recommended for empirical therapy of acute otitis media.[10] Although it is not approved for use, it can be effective therapy for sinusitis caused by *H. influenzae*, susceptible pneumococci, and *M. catarrhalis*. Albeit uncommon, its principal use today in pediatrics is for the treatment of acute otitis media caused by susceptible pathogens in patients with β-lactam hypersensitivity.

Metronidazole

Metronidazole is a synthetic imidazole available since 1959. It was first introduced for the treatment of *Trichomonas vaginalis*. Metronidazole has antiprotozoal and anaerobic activity.

Mechanisms of Action. Metronidazole enters the cells by passive diffusion, and the nitro side chain undergoes chemical reduction by the pyruvate-ferredoxin reductase complex into a toxic nitro radical that subsequently causes DNA destabilization and rupture with cell death. It has been postulated that metronidazole has anti-inflammatory and immunonomodulator effects by

decreasing neutrophil generation of hydrogen peroxide and hydroxyl radicals.

Mechanisms of Resistance. Bacteria become resistant to metronidazole by changes in the enzymes implicated in the activation of the antibiotic. Some bacteria contain *nim* genes that code for an inactivating enzyme that reduces the nitro group into an inactive amine. These genes may be present in plasmids and chromosomes.

Pharmacokinetics. Metronidazole has good oral absorption with a bioavailability of at least 90 percent. It is available in oral (i.e., tablets and capsules) and parenteral forms. It is also available for topical use (i.e., vaginal and rectal). It has good penetration and a low degree of protein binding (<20%), for which it has wide distribution, including good concentrations in CSF. Its half-life is approximately 8 hours. Metronidazole is eliminated mainly by renal clearance (60% to 80%), and 6 to 15 percent is eliminated unchanged in feces. It is cleared by hemodialysis but does not require dose adjustment with renal insufficiency. In cases of severe hepatic dysfunction, the dose should be adjusted because clearance can be diminished.

Indications for Use. Metronidazole is the treatment of choice for *T. vaginalis*, *Giardia duodenalis*, *Entamoeba histolytica*, bacterial vaginosis, and *C. difficile*–associated disease. Metronidazole has been widely used in pediatrics for the treatment of anaerobic infections, including intra-abdominal and head and neck infections (including brain abscess), despite its lack of FDA approval for these indications. For these infections a combination regimen should be used because metronidazole does not have aerobic activity. Metronidazole is used for the treatment of *H. pylori* ulcerative disease, in combination with other antibiotics and a proton pump inhibitor.[194] Safety and effectiveness of metronidazole in children have not been established, except for the treatment of amebiasis with oral metronidazole.

Adverse Effects. Gastrointestinal disturbances are the most frequent adverse effects, including nausea and diarrhea. Less frequently, dizziness, headache, loss of appetite, emesis, and abdominal pain have been reported. Other rare effects include taste changes, constipation, dry mouth, glossitis or stomatitis, headache, dark urine, pruritus, rash, insomnia, arthralgias, fever, and reversible hematologic disturbances, including leukopenia and thrombocytopenia. The parenteral form may cause phlebitis at the site of injection. With high doses, neurologic effects may be seen, including ataxia, confusion, and irritability.[44] The neurologic side effects require discontinuation of the drug. In older patients, the concomitant consumption of metronidazole and alcohol can produce a disulfiram effect.

SELECTED ASPECTS OF THE ADMINISTRATION OF ANTIMICROBIAL AGENTS

DOSAGE SCHEDULES FOR INFANTS AND CHILDREN

Dosage schedules of antimicrobial agents commercially available in the United States for infants (beyond the newborn period) and children are listed in Table 235-10. The list is subdivided into dosage schedules for mild-to-moderate and for severe disease. Oral regimens are used for mild-to-moderate infections caused by susceptible organisms in areas that are well vascularized and in which adequate concentrations of drug are achieved at the site of infection. Parenteral administration should be considered for severe infections, especially those caused by less susceptible organisms that produce disease in areas in which diffusion of drug is limited.

DOSAGE SCHEDULES FOR NEWBORN INFANTS

The clinical pharmacology of antimicrobial agents administered to newborn infants is unique and cannot be extrapolated from data derived from older children or adults. The physiologic and metabolic processes that affect the distribution, metabolism, and excretion of drugs undergo rapid changes during the child's first few weeks of life. The increased efficiency of kidney function after the infant's first 7 days requires an increase in dosage and a decrease in the interval between doses of penicillins and aminoglycosides for maintaining therapeutic concentrations of drug in blood and tissues. Thus, different dosage schedules are provided for the first week of life and for the subsequent weeks of the neonatal period (Tables 235-11 and 235-12). With survival of premature infants with very low birth-weights, more data are needed on the use of antimicrobial agents in these infants with immature metabolic and physiologic mechanisms.[251] Dosages of antibiotics in these preterm infants, especially those weighing less than 1000 g, are unclear for many agents, and measurement of serum concentrations should be considered for drugs such as vancomycin and the aminoglycosides.

SHOULD DOSAGES BE DETERMINED BY WEIGHT OR BY SURFACE AREA?

In most standard pediatric texts and in the package inserts prepared by manufacturers, dosages of antibiotics for children are based on body weight. Body surface area

TABLE 235-10 **Daily Dosage Schedules for Antimicrobial Agents in Pediatric Patients Beyond the Newborn Period**

Agent, Generic (Trade Name)	Route	Mild-to-Moderate Infections*	Severe Infections*
Penicillin G, crystalline (numerous)	IV, IM	100,000-250,000 U ÷ into four doses	250,000-450,000 U ÷ into six doses
Penicillin G, procaine (numerous)	IM	50,000 U once daily (congenital syphilis); 300,000 (<60 lb) or 600,000-1,000,000 U (≥60 lb) ÷ into one or two doses for group A streptococcal infections	Inappropriate
Penicillin G, benzathine (Bicillin)	IM	300,000-600,000 U (<60 lb)† or 900,000 U (≥60 lb)† for group A streptococcal infections; 50,000 U/kg (up to 2,400,000 U)† for syphilis	Inappropriate
Penicillin V, phenoxymethyl penicillin (numerous)	PO	25-50 mg ÷ into three or four doses	Inappropriate
Penicillinase-resistant Penicillins			
Cloxacillin (Cloxapen)	PO	50-100 mg ÷ into four doses	Inappropriate
Dicloxacillin (Dynapen, Dycill, Pathocil)	PO	25-50 mg ÷ into four doses	Inappropriate
Methicillin (Staphcillin)‡	IV, IM	100-200 mg ÷ into four doses	200-300 mg ÷ into four to six doses
Nafcillin (Nafcil, Unipen, Nallpen)	IV, IM	50-100 mg ÷ into four doses	100-200 mg ÷ into four to six doses
Oxacillin (Prostaphlin, Bactocill)	IV, IM	100-150 mg ÷ into four doses	150-200 mg ÷ into four to six doses
Aminopenicillins			
Amoxicillin (numerous)	PO	25-90 mg ÷ into two or three doses	Inappropriate
Amoxicillin + clavulanate (Augmentin)	PO	45-90 mg ÷ into two or three doses	Inappropriate
Ampicillin (numerous)	IV, IM	100-200 mg ÷ into four doses	200-400 mg ÷ into four to six doses
	PO	50-100 mg ÷ into 4 doses	Inappropriate
Ampicillin + sulbactam (Unasyn)	IV	100-200 mg of ampicillin ÷ into four doses	200-400 mg of ampicillin ÷ into four to six doses
Extended-Spectrum Penicillins			
Mezlocillin (Mezlin)	IV, IM	Inappropriate	200-300 mg ÷ into four to six doses
Piperacillin (Pipracil)	IV, IM	Inappropriate	200-300 mg ÷ into four to six doses
Piperacillin + tazobactam (Zosyn)	IV	Inappropriate	240-300 mg of piperacillin ÷ into three to four doses
Ticarcillin (Ticar)	IV, IM	100-200 mg ÷ into 4 doses	200-300 mg ÷ into four to six doses
Ticarcillin + clavulanate (Timentin)	IV	Inappropriate	200-300 mg ÷ into four to six doses
Monobactams			
Aztreonam (Azactam)	IV, IM	90 mg ÷ into three doses	120 mg ÷ into four doses
Cephalosporins			
Cefadroxil (Duricef)	PO	30 mg ÷ into two doses	Inappropriate
Cefazolin (Ancef, Kefzol)	IV, IM	50 mg ÷ into three doses	50-100 mg ÷ into three or four doses
Cephalexin (Keflex, Keftab)	PO	25-100 mg ÷ into four doses	Inappropriate
Cefaclor (Ceclor)	PO	20-40 mg ÷ into two or three doses	Inappropriate
Cefoxitin (Mefoxin)	IV	Inappropriate	80-160 mg ÷ into four to six doses
Cefprozil (Cefzil)	PO	15-30 mg ÷ into two doses	Inappropriate
Ceftibuten (Cedax)	PO	9 mg once daily	Inappropriate
Cefuroxime (Kefurox, Zinacef)	IV, IM	Inappropriate	100-150 mg ÷ into three or four doses
Cefuroxime axetil (Ceftin)	PO	20-30 mg ÷ into two doses	Inappropriate
Loracarbef (Lorabid)	PO	15-30 mg ÷ into two doses	Inappropriate
Cefdinir (Omnicef)	PO	14 mg ÷ into one or two doses	Inappropriate
Cefditoren (Spectracef)	PO	200-400 mg twice daily†,§	Inappropriate
Cefixime (Suprax)	PO	8 mg ÷ into one or two doses	Inappropriate
Cefotaxime (Claforan)	IV, IM	Inappropriate	100-180 mg ÷ into four to six doses
Cefpodoxime proxetil (Vantin)	PO	10 mg ÷ into two doses	Inappropriate
Ceftazidime (Fortaz, Tazicef, Tazidime, Ceptaz)	IV, IM	Inappropriate	100-150 mg ÷ into three doses

TABLE 235-10 **Daily Dosage Schedules for Antimicrobial Agents in Pediatric Patients Beyond the Newborn Period** (Continued)

Agent, Generic (Trade Name)	Route	Mild-to-Moderate Infections*	Severe Infections*
Ceftriaxone (Rocephin)	IV, IM	Inappropriate	50-100 mg ÷ into one or two doses
Cefepime (Maxipime)	IV, IM	Inappropriate	100-150 mg ÷ into two or three doses
Carbapenems			
Ertapenem (Invanz)	IV, IM	Inappropriate	30 mg ÷ into two doses
Imipenem-cilastatin (Primaxin)	IV, IM	Inappropriate	60-100 mg ÷ into four doses
Meropenem (Merrem)	IV	Inappropriate	60-120 mg ÷ into three doses
Macrolides			
Azithromycin (Zithromax)	PO	10 mg on day 1, then 5 mg thereafter; 12 mg for pharyngitis	Inappropriate
Clarithromycin (Biaxin)	PO	15 mg ÷ into two doses	Inappropriate
Erythromycin base (numerous)	PO	30-50 mg ÷ into four doses	Inappropriate
Erythromycin estolate (Ilosone)	PO	30-50 mg ÷ into four doses	Inappropriate
Erythromycin ethylsuccinate (E.E.S., EryPed, Erythro)	PO	30-50 mg ÷ into four doses	Inappropriate
Erythromycin gluceptate (Ilotycin)	IV	Inappropriate	20-50 mg ÷ into four doses
Erythromycin lactobionate (Erythrocin)	IV	Inappropriate	20-50 mg ÷ into four doses
Erythromycin stearate (Erythrocin, Erythrocot, MyE)	PO	30-50 mg ÷ into four doses	Inappropriate
Lincosamides			
Clindamycin (Cleocin)	IV, IM	Inappropriate	20-40 mg ÷ into three or four doses
	PO	8-20 mg ÷ into three or four doses	Inappropriate
Vancomycin (Vancocin)	IV	Inappropriate	40-60 mg ÷ into four doses
Aminoglycosides			
Amikacin (Amikin)	IV, IM	Inappropriate	15-22.5 mg ÷ into three doses
Gentamicin (Garamycin)	IV, IM	Inappropriate	5-7.5 mg ÷ into three doses‖
Kanamycin (Kantrex)	IV, IM	Inappropriate	15-30 mg ÷ into three doses
Netilmicin (Netromycin)	IV, IM	Inappropriate	5-7.5 mg ÷ into three doses
Paramomycin (numerous)	PO	25-35 mg ÷ into three doses	Inappropriate
Streptomycin (numerous)	IM	Inappropriate	20-40 mg ÷ into one or two doses
Tobramycin (Nebcin)	IV, IM	Inappropriate	6-7.5 mg ÷ into three to four doses
Tetracyclines			
Doxycycline (numerous)	PO	2.2-4.4 mg ÷ into one or two doses	Inappropriate
Tetracycline (numerous)	PO	25-50 mg ÷ into four doses	Inappropriate
Chloramphenicol (Chloromycetin)	IV	Inappropriate	50-100 mg ÷ into four doses
	PO	Inappropriate	50-100 mg ÷ into four doses
Sulfonamides			
Erythromycin ethylsuccinatesulfisoxazole (Pediazole, Eryzole)	PO	50 mg erythromycin/150 mg sulfa ÷ into four doses	Inappropriate
Sulfadiazine (numerous)	PO	100-150 mg ÷ into four doses	Inappropriate
Sulfisoxazole (Gantrisin)	PO	150 mg ÷ into four doses	Inappropriate
Trimethoprim-sulfamethoxazole (Bactrim, Septra, Sulfatrim, Cotrim)	PO	8-12 mg trimethoprim/40-60 mg sulfamethoxazole ÷ into two doses	Inappropriate
	IV	Inappropriate	10-20 mg trimethoprim/50-100 mg sulfamethoxazole ÷ into four doses
Fluoroquinolones			
Ciprofloxacin (Cipro)	PO	20-30 mg ÷ into two doses	Inappropriate
	IV	Inappropriate	20-30 mg ÷ into two doses
Rifampin (Rifadin, Rimactane)	PO	10-20 mg ÷ into one or two doses	20 mg ÷ into two doses
	IV	Inappropriate	20 mg ÷ into two doses

*Dosages should be adjusted according to serum drug concentrations.
†Single daily dosing is used commonly in neonates: 3-3.5 mg/kg (<35 wk) or 4 mg/kg (≥35 wk).
‡At 28 days of life, vancomycin is administered at 20 mg/kg per dose; the interval remains the same.
IM, Intramuscularly; *IV,* intravenously.

correlates more closely with extracellular fluid volume. Some investigators suggest that more predictable serum concentrations can be achieved by using calculations of dosages based on surface area than by using those based on weight.[135] This method may be more reliable for drugs that are distributed in extracellular fluid, such as aminoglycosides, especially when they are prescribed for obese or malnourished children. Currently, however, the convenience of calculating dosage on the basis of weight appears to be the more important consideration.

USE OF ORAL PREPARATIONS FOR SERIOUS INFECTIONS

Oral preparations of antimicrobial agents vary in their degree of absorption from individual to individual and within an individual, depending on the illness being treated and the formulation used. Because higher and more consistent serum concentrations of drug are achieved after parenteral administration, parenteral routes are preferable for serious infections. Sequential parenteral-oral antimicrobial therapy may be an option in patients with uncomplicated pneumonia, pyelonephritis, and intra-abdominal, skin and soft tissue, and suppurative skeletal infections.[207] Results of studies of orally administered antibiotics in children with skeletal infections indicate that this mode of administration can be used successfully for a portion of the therapeutic course.[227,299]

Specific guidelines for oral treatment of serious infections are recommended: (1) the patient should be able to swallow and retain the medication; (2) the dosage should be sufficiently large to provide adequate bactericidal concentrations of drug at the site of infection for at least 50 percent of the dosing interval for β-lactams; and (3) when possible, it is advisable to have the hospital laboratory determine serum antimicrobial concentrations. When this is not possible, careful followup is mandatory, and measurements of inflammatory indices, such as the erythrocyte sedimentation rate and C-reactive protein, are very useful in determining resolution of the infection.

Oral therapy can be considered for patients with osteomyelitis and suppurative arthritis only after an initial period of parenteral therapy (≥5 to 7 days), after results are available from cultures and susceptibility tests, and after the patient shows definite signs of resolution of inflammation. Oral therapy should be initiated before discharge from the hospital to ascertain compliance, determine serum antimicrobial concentrations when available, and observe for significant side effects that would preclude use of the oral antibiotic.

FOOD INTERFERES WITH THE ABSORPTION OF SOME ORAL ANTIBIOTICS

The absorption of some oral antimicrobial agents is decreased significantly when the drug is taken with food or near mealtime. These drugs include unbuffered penicillin G, penicillinase-resistant penicillins (i.e., nafcillin, oxacillin, cloxacillin, and dicloxacillin), ampicillin, and lincomycin. Dairy products and other foods or medications containing calcium or magnesium salts interfere with the absorption of tetracyclines. Absorption of penicillin V, buffered penicillin G, amoxicillin, cephalexin, cefaclor, chloramphenicol, erythromycin, and clindamycin is affected only slightly by food. When absorption is affected by the concurrent ingestion of food, antibiotics should be taken 1 or more hours before or 2 or more hours after meals. A dosage schedule of four times daily, rarely used for common infections, can be arranged for the drug to be given on arising, 1 hour before lunch and supper, and at bedtime. Most orally administered antibiotics can be administered twice or three times daily, a schedule that is accommodated easily by most parents.

INTRAVENOUS VERSUS INTRAMUSCULAR ADMINISTRATION

Although a brief period occurs when the serum antimicrobial concentration is higher after intravenous administration of an antimicrobial agent than after intramuscular administration, no therapeutic advantage of intravenous

as opposed to intramuscular administration has been demonstrated. Intravenous administration should be used if the patient is in shock or is suffering from a bleeding diathesis. When prolonged parenteral therapy is anticipated, the pain of injection and the small muscle mass of infants and young children preclude the intramuscular route and render intravenous therapy preferable. The physician must be alert for thrombophlebitis, which can result from prolonged intravenous administration, and for sterile abscesses, which can develop after intramuscular administration.

Chloramphenicol, erythromycin, linezolid, tetracyclines, and vancomycin should be administered intravenously rather than intramuscularly. Chloramphenicol was thought to be absorbed poorly from intramuscular sites, although more recent data suggested that such is not the case. Intramuscular injection of parenteral tetracyclines and erythromycin causes local irritation and pain, and intramuscular injection of vancomycin causes tissue necrosis. Care should be given to the administration of intramuscular injections.[28,195] Sites that minimize the risk for local neural, vascular, or tissue injury should be selected. The preferred site varies with the age of the child: the upper anterolateral aspect of the thigh in infants, the ventrogluteal area in children older than 2 years of age, and the deltoid area for older children. Inadvertent intra-arterial injection of benzathine penicillin G can cause tissue damage.

"PUSH" VERSUS "STEADY" OR "CONTINUOUS DRIP" INTRAVENOUS ADMINISTRATION

Antimicrobial agents can be administered intravenously by the "push" method, in which case the drug is infused in 5 to 15 minutes; by "steady drip" in 1 to 2 hours; or by "continuous drip," whereby the drug is given throughout the period of administration. The push method results in high antibacterial activity in serum for short periods, whereas the steady and continuous drip methods produce lower but more sustained activity. The risk for development of adverse effects influences whether an antimicrobial agent should be administered by push or by steady drip. Pharmacodynamic studies suggest optimization of bactericidal activity when aminoglycosides are given by push once daily because the activity of these agents is concentration-dependent. By contrast, β-lactams are given preferably in several doses or by a continuous drip to maintain concentrations of drug at the infection site that exceed the MIC of the pathogen for 50 percent or longer of the dosing interval (time-dependent pharmacodynamic principle). Rapid administration (<5 minutes) of large intravenous doses of penicillin should be avoided because of possible adverse CNS effects. Aminoglycosides given by the intravenous route should be infused in 20 to 60 minutes to obtain optimal peak concentrations. Antimicrobial activity, especially for penicillins, can deteriorate if drugs are kept in solution at room temperature for prolonged periods, as may occur with use of the continuous drip method. Fresh solutions of penicillins should be administered every 6 to 8 hours when the continuous drip method is used.

DIFFUSION OF ANTIMICROBIAL AGENTS ACROSS BIOLOGIC MEMBRANES

Diffusion of any drug across a biologic membrane depends on the molecular size of the drug, the degree of protein binding (only the unbound portion of the drug crosses), the degree of ionization at physiologic pH (only the unionized portion is available for equilibration), and solubility in lipids. Thus, the lipid solubility of the unionized and unbound fraction of an antimicrobial agent determines the capability of the drug to diffuse to the site of infection. Antibiotics usually are not distributed evenly throughout the body.[231,232]

Diffusion of antimicrobial agents from blood into a joint space, pleural and pericardial fluid, and middle ear fluid is relatively unimpeded, and high concentrations of many drugs are achieved in these sites after systemic administration. More than 60 percent of the peak serum concentration of various penicillins and cephalosporins is present in the inflamed joint space.[227] Loculations of fluid in the presence of fibrous adhesions may limit the passage of antimicrobial agents into infected areas.

Diffusion of antibiotics from blood into CSF or into the aqueous humor of the eye is limited. Drugs that are highly soluble in lipids, unionized, and minimally bound to proteins (e.g., chloramphenicol, isoniazid, rifampin, and sulfonamides) pass into CSF in high concentrations, even in the absence of inflammation, whereas drugs such as the macrolides diffuse into CSF little, if at all. Fluoroquinolones pass readily into the CSF space but do not have an indication for use for meningitis in children. Penicillins, cephalosporins, and aminoglycosides pass more effectively into CSF when the membrane is inflamed; variable, but often low, concentrations of drug in CSF can be present even in the early stages of meningitis. The β-lactams are pumped actively out of the CSF space by the choroid plexus, a process that is inhibited partially by inflammation.

DURATION OF THERAPY

Physicians must rely on empirically derived schedules of therapy for rapid and complete resolution of disease and minimal risk in terms of clinical or microbiologic failure or drug toxicity. Numerous studies evaluating the duration of therapy have been performed for streptococcal pharyngitis. The results are consistent in suggesting that the following are appropriate: 10 days of oral therapy with penicillins, cephalosporins, or macrolides; 5 days of azithromycin; or a single intramuscular dose of benzathine penicillin G. Opinions vary and data are conflicting regarding the duration of treatment for diseases such as osteomyelitis, suppurative arthritis, and infections of the

urinary tract. Radetsky[252] wrote an enlightening history of the recommendations for the duration of treatment in bacterial meningitis and pointed out: "Even in the absence of specific data certain numbers have an unaccountable power to satisfy and reassure. 7, 10, 14 and 21 days have consistently appeared. Even in the trials performed at the dawn of the antimicrobial era, these numbers were chosen."

DOSAGE SCHEDULES IN CHILDREN WITH RENAL OR HEPATIC INSUFFICIENCY

The kidneys are the major organs of excretion for most antimicrobial agents, including penicillins, cephalosporins, aminoglycosides, and tetracyclines (with the exception of doxycycline). Because impaired excretion can result in high and possibly toxic serum and tissue antimicrobial concentrations, alterations in dosage schedules should be considered in children with diminished renal function. Antibiotics that require careful dosage adjustment for renal impairment include aminoglycosides, ciprofloxacin, imipenem-cilastatin, meropenem, piperacillin, tetracyclines, ticarcillin, TMP-SMX, and vancomycin. Agents requiring dosage adjustments only when renal failure is severe include most penicillins, cephalosporins, and clindamycin. Drugs that are eliminated by nonrenal mechanisms and therefore do not require adjustment of the dosage schedule for renal impairment include chloramphenicol, cloxacillin, dicloxacillin, doxycycline, erythromycin (including the newer macrolides), metronidazole, linezolid, nafcillin, oxacillin, and rifampin.[313]

Dosage schedules for patients with renal insufficiency can be altered by administering the usual dosage for the initial dose and increasing the interval between doses or decreasing individual doses (or both, in the case of renal shutdown). Although numerous guidelines have been developed to assist the physician, these formulas have been generated from studies of adults with renal impairment, and pediatricians must be cautious in adapting the formulas for use in infants and young children.[313] Serum antimicrobial concentrations should be monitored when aminoglycosides, vancomycin, and other drugs of potential toxicity are administered to children with renal insufficiency. Serum specimens are obtained at the time of the anticipated peak and trough concentrations on the first day and repeated on subsequent days to ensure a safe and effective dosage schedule.

Hepatic disorders can alter plasma protein binding, tissue binding, hepatic metabolism, and the distribution of antimicrobials that are metabolized or excreted by the liver.[309] Few data exist regarding adjustment of dosage schedules for antibiotics that are metabolized by the liver in patients with hepatic insufficiency.[183] It would be prudent to avoid the use of tetracyclines and to exercise caution when prescribing chloramphenicol, clindamycin, metronidazole, macrolides, rifampin, and penicillinase-resistant penicillins to patients with underlying hepatic disease.

TOPICAL USE OF ANTIMICROBIAL AGENTS

Topical antimicrobial agents are used for a variety of indications: bacitracin or polymyxin ointments are available (in many cases without prescription) for first aid of minor cuts, abrasions, and burns; tetracycline, erythromycin, and clindamycin have been used for the treatment of pustular acne; and metronidazole is approved for the topical treatment of inflammatory lesions and erythema associated with rosacea. Erythromycin, chloramphenicol, sulfonamide, gentamicin, tobramycin, tetracycline, and a combination of TMP and polymyxin B ointment or drops are used for the treatment of conjunctivitis, styes, and other minor infections of the eye. Silver nitrate drops or erythromycin or tetracycline ointment is used for the prevention of gonococcal ophthalmia in newborn infants. A controlled trial involving newborn infants in Africa demonstrated equivalent or superior efficacy of a 2.5 percent ophthalmic solution of povidone-iodine in contrast to topical silver nitrate or erythromycin for prophylaxis against ophthalmia neonatorum caused by *C. trachomatis*, *N. gonorrhoeae*, staphylococci, or gram-negative bacteria.[148] Ofloxacin drops (Floxin Otic) are approved for the treatment of otitis externa, chronic suppurative otitis media, and acute otitis media in children with tympanostomy tubes.[35] Ciprofloxacin and dexamethasone otic solution (Ciprodex) is approved for children 6 months of age and older who have tympanostomy tubes, to treat acute otitis media caused by *S. aureus*, *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *P. aeruginosa*, as well as acute otitis externa caused by *S. aureus* and *P. aeruginosa*. Mupirocin is effective in vitro against most *S. aureus* (including methicillin-resistant strains) and group A streptococci and is approved for the treatment of impetigo. At present, approximately 10 percent of CAMRSA strains are resistant to mupirocin; in some areas, the rate is as high as 30 percent. Mupirocin applied to the anterior nares may be of value in eradicating nasal carriage of methicillin-resistant staphylococci. However, the few well-designed controlled studies that exist do not support the routine use of mupirocin, except possibly for patients undergoing dialysis, because prolonged use of mupirocin has been associated with resistance to this agent, and recolonization is a common occurrence.[68] Most antibiotics used topically, such as bacitracin, neomycin, and polymyxin B, are of limited use as systemic agents. Retapamulin ointment (Altabax), a pleuromutilin antibacterial, was approved by the FDA in 2007 for topical treatment of impetigo caused by *S. aureus* (methicillin-susceptible isolates only) or *S. pyogenes* in patients aged 9 months or older. The dosage is twice daily applications for 5 days.

Absorption after application to the conjunctivae or large areas of denuded skin can be significant, but application to normal skin does not result in detectable concentrations of antimicrobial activity in blood or urine. Sensitization does not appear to be an important problem with most topical antibiotics, although some patients with chronic dermatoses may react to certain agents such

as neomycin. Antimicrobial agents of value for systemic use should not be applied extensively to the surface of the body or used routinely in closed units (e.g., burn units) because of the risk for inducing resistance.

The Committee on Drugs of the American Academy of Pediatrics concluded that topical antimicrobial agents may prevent infection after minor cuts, abrasions, and burns, but in most instances, gentle cleansing of minor wounds and burns is sufficient antisepsis.[7] Systemic antibiotics, rather than topical drugs, are recommended for chronic pyoderma, including impetigo, especially when more than several lesions are present.

Intermittent administration of inhaled tobramycin (twice daily for 4 weeks followed by 4 drug-free weeks) is indicated for the management of children and adults with cystic fibrosis and *P. aeruginosa* infection. Clinical data from a large, randomized, placebo-controlled trial indicates that tobramycin treatment improves pulmonary function, decreases the density of *P. aeruginosa* in sputum, reduces the risk for hospitalization, and is well tolerated. The diminished microbial reduction during the third cycle of treatment was not explained by the development of resistance to tobramycin.[255]

The use of antimicrobial-coated central venous catheters is not accepted practice in pediatrics, but limited evidence supports its potential usefulness, particularly if rates of catheter-related bloodstream infections exceed 3.3/1000 catheter days and if standard protective procedures already have been implemented.[237] Rates of bacterial colonization and bloodstream infections associated with the use of central venous catheters in high-risk adult patients were found to be lower in patients whose catheters were impregnated with minocycline and rifampin than in those impregnated with chlorhexidine and silver sulfadiazine.[85]

CURRENT USE OF ANTIMICROBIAL AGENTS FOR PROPHYLAXIS

Chemoprophylaxis refers to the use of drugs to prevent infection. Antimicrobial treatment refers to the use of drugs after infection has taken place or when early signs of infectious disease are present or infection is suspected. The use of antimicrobial agents for prophylaxis has proved to be of value in many circumstances (Table 235-13) and currently is considered to be of probable value or is investigational for the prevention of infections in many other situations. Prophylaxis is of greatest value when the following criteria are met: use of a single drug with a narrow spectrum of activity, use of a drug with limited side effects or toxicity, and prevention of colonization by an organism of known susceptibility and one that is unlikely to become resistant during the period of drug use. Current recommendations from the American Academy of Pediatrics include the following circumstances: (1) site-related infections: otitis media, urinary tract infection, and endocarditis; (2) exposed host: *B. pertussis* exposure, *N. meningitidis* exposure, traveler's diarrhea, perinatal group B streptococci exposure, bite wound (i.e., human, animal, or reptile), infants born to HIV-infected mothers, close exposure to influenza in unimmunized hosts, susceptible contacts of index cases of invasive *H. influenzae* type b disease, and exposure to aerosolized spores of *B. anthracis;* (3) vulnerable host (pathogen): oncology patients (i.e., with *P. jirovecii* or fungi), HIV-infected children (i.e., with *P. jirovecii* or polysaccharide encapsulated bacteria), preterm neonates (i.e., with *Candida* sp.), anatomic or functional asplenia (i.e., with polysaccharide encapsulated bacteria), chronic granulomatous disease (i.e., with *S. aureus* and certain

TABLE 235-13 **Antimicrobial Prophylaxis in Children**

Prevention of Infection in Certain Patients	Antimicrobial Agent
Group A streptococcal infection in patients with a history of rheumatic fever	Benzathine penicillin G IM, penicillin V PO
Bacterial endocarditis in patients at risk during surgical procedures:	
Dental procedures, surgery on the upper respiratory tract	Amoxicillin PO; clindamycin, cephalexin, cefadroxil, azithromycin, or clarithromycin in penicillin-allergic patients
Gastrointestinal or genitourinary tract surgery or instrumentation	Amoxicillin PO, ampicillin IV, ampicillin plus gentamicin, or vancomycin plus gentamicin (for penicillin-allergic patients)
Neonatal sepsis caused by group B streptococcus	Penicillin (preferred) or ampicillin IM or IV (intrapartum)
Gonococcal ophthalmia in newborn infants	Silver nitrate or erythromycin ophthalmic ointment
Meningococcal disease in contacts	Rifampin, ceftriaxone
Haemophilus influenzae type b disease in contacts	Rifampin
Recurrent episodes of acute otitis media	Amoxicillin, sulfisoxazole
Postoperative infections	Penicillinase-resistant penicillins or first- or second-generation cephalosporins
Tuberculosis infections in close contacts	Isoniazid
Recurrent urinary tract infections	Trimethoprim-sulfamethoxazole, nitrofurantoin
Sepsis in patients with functional asplenia	Penicillin, amoxicillin, trimethoprim-sulfamethoxazole

IM, Intramuscularly; *IV,* intravenously; *PO,* orally.

other catalase-positive bacteria and fungi), congenital immunodeficiencies (i.e., with various pathogens), and rheumatic fever (i.e., with group A streptococci).[249]

USE OF ANTIMICROBIAL AGENTS FOR CHILDREN IN SCHOOL OR GROUP DAYCARE

Infants and children usually return to their school or daycare during a course of antimicrobial therapy. Because of problems with the administration of drugs outside the home, physicians should prescribe medications that are given infrequently, are relatively stable at ambient temperatures, and need only simple directions. Drugs that are administered in once- or twice-daily schedules are preferred. Chewable tablets, when available, may be of value in reducing the need for the school or daycare provider to measure specific amounts of liquid suspension and to refrigerate suspensions. Single-dose regimens, such as intramuscular benzathine penicillin G for group A streptococcal infections, may be advantageous. Guidelines for administration of medications in schools have been published by the Committee of School Health of the American Academy of Pediatrics and should be useful to the physician for prescribing drugs to children who attend school.[9]

RESTRICTION ON USE OF ANTIMICROBIAL AGENTS FOR INFANTS AND CHILDREN

Many antimicrobial agents are approved for use in adults but have not been approved by the FDA for use in infants and children. The reasons for lack of approval drugs with insufficient experience in children, such as tigecycline (Tygacil); agents with real or suspected toxicity in children (e.g., damage to articular cartilage in juvenile animals associated with administration of the fluoroquinolones) that should be used only when necessary; and antibiotics for which the manufacturers have chosen not to submit data on use in children to the FDA, such as metronidazole (Flagyl), piperacillin (Pipracil), and cefotetan (Cefotan). These last three agents appear to be safe and effective in infants and children as a result of use by pediatricians, but no well-controlled studies of their efficacy or safety in this age group have been performed. Although a drug that has been approved for adults may be used in children at the discretion of the physician, the prudent physician chooses to use such a drug only when it is uniquely appropriate for the infectious illness and records the basis for choice of the unapproved drug.

Seven antibiotics were approved for use in adults and have potential usefulness in the management of some pediatric patients with infections caused by multidrug-resistant pathogens. Daptomycin (Cubicin) is a cyclic lipopeptide that was approved by the FDA in 2003 for intravenous treatment of adults with complicated skin and skin structure infections caused by gram-positive organisms, including MRSA, in a single daily dose of 4 mg/kg. Daptomycin was approved in 2006 for adults with methicillin-susceptible or methicillin-resistant bacteremia or right-sided endocarditis in a dose of 6 mg/kg daily for a minimum of 2 to 6 weeks. It has been shown to be inferior to comparator agents for community-acquired pneumonia, likely as a result of inactivation of daptomycin in the presence of pulmonary surfactant.[269] Although experience with daptomycin is meager in pediatrics, the drug does appear to be effective in the setting of persistent bacteremia in children with disseminated MRSA infection. Dosages of 8 to 10 mg/kg daily are generally used in these patients.

Quinupristin-dalfopristin (Synercid), a semisynthetic streptogramin, has synergistic activity against the same organisms as does linezolid and has been used extensively in adults in Europe. The dosage for children is 7.5 mg/kg intravenously three times daily. The drug has been well tolerated by children; diarrhea is the most common adverse effect. Telithromycin (Ketek) was approved in 2004 for use in adults. It is a semisynthetic ketolide antibacterial that differs chemically from the macrolide group by lack of L-cladinose at position 3 of the erythronolide A ring. Telithromycin is indicated for enteral treatment of adults with mild-to-moderate community-acquired pneumonia caused by common respiratory tract pathogens, including multidrug-resistant *S. pneumoniae* and atypical bacteria. In 2007, the FDA removed two previously approved indications, namely, acute exacerbations of chronic bronchitis and acute bacterial sinusitis because telithromycin has been associated with severe liver toxicity in adults. Its use is contraindicated in patients with myasthenia gravis. Safety and efficacy have not been established in children.

Tigecycline (Tygacil) is a glycylcycline related to minocycline that was approved by the FDA in 2005 for intravenous use in the treatment of adults with complicated intra-abdominal infections and complicated skin and skin structure infections caused by aerobic and anaerobic gram-positive and gram-negative bacteria, including MRSA.

In 2007, doripenem was approved for use in adults with complicated intra-abdominal infections and complicated urinary tract infections. It has activity against MSSA, penicillin-susceptible and nonsusceptible *S. pneumoniae*, and *E. faecalis*. It also has activity against ESBL-producer gram-negative bacteria. Telavancin was approved by the FDA in 2009 for treatment of complicated skin and skin structure infections in adults and is active against resistant bacteria, including MRSA, GISA, and *S. pneumoniae*. Ceftaroline fosamil is a broad-spectrum cephalosporin that received FDA approval in 2010 for the treatment of acute bacterial skin and skin structure infections and community-acquired pneumonia in adults. It has activity against MRSA, GRSA, multidrug-resistant *S. pneumoniae*, and non-ESBL enteric gram-negative organisms, including *E. coli* and *K. pneumoniae*. Ceftaroline is currently being evaluated in children.

HOME INTRAVENOUS ANTIBIOTIC THERAPY

Home intravenous antibiotic therapy is now available in most communities and permits discharge from the hospital earlier than in the past. The safety, effectiveness, and cost-efficiency of such a program have been proved, and these factors are of particular value for children who require 4 to 6 weeks of therapy for osteomyelitis or suppurative arthritis or who have chronic disease that can be managed in the home, such as cystic fibrosis or malignant disease. In many cases, home care enables the patient to resume normal activities, including return to school. The following are factors that are necessary before consideration of home care:

1. Availability of a team that includes the physician, the pharmacist, a vendor who will supply the drug and supplies, and an intravenous specialty nurse
2. A disease that is stable and requires only continued antimicrobial therapy
3. Unavailability of a suitable oral antibacterial agent (see the earlier discussion on use of oral preparations for serious infections) and availability of a stable parenteral antibiotic with low toxicity that the patient can tolerate (as demonstrated in the hospital) and preferably with a long half-life to allow infrequent dosing
4. A member of the household who is able to administer the antibiotic and provide aseptic care of the venous access device
5. Appropriate follow-up that can be maintained for monitoring safety and effectiveness

If problems with venous access arise and ceftriaxone is appropriate therapy, the drug can be administered successfully at home by the intramuscular route once daily by a nurse.[117,267]

DRUG–DRUG INTERACTIONS

Drug–drug interactions can lead to therapeutic failure because of lack of effective activity of one or both drugs or serious adverse events resulting from toxic serum concentrations of one or both drugs.[118] Most children do not require daily medications for chronic diseases; thus, drug–drug interactions occur less commonly in pediatric than in geriatric patients, but the potential for interactions exists and must be considered when prescribing antibiotics. Because drug–drug interactions are not limited to prescription medications, inquiry into the use of over-the-counter medications should be made. Mechanisms for drug–drug interactions are classified as follows: physiochemical, in which one drug is physically incompatible in solution with another; pharmacokinetic, whereby one drug interferes with the absorption, distribution, metabolism, or excretion of the other; and pharmacodynamic, whereby one drug affects the activity of a second drug. Examples of each mechanism include inactivation of aminoglycosides by extended-spectrum penicillins, decreased absorption of tetracyclines with coadministration of antacids, antagonism of sulfonamide activity by procaine as a result of competition for PABA binding sites, and interference with the CYP450 oxidase enzyme system as observed with rifampin and macrolide drugs or with the azole antifungal agents and cyclosporine.

SUMMARY AND CONCLUSIONS

A summary of the information contained in this chapter is presented in the following questions that the physician must consider for appropriate use of antimicrobial agents in children:

1. Before the drug is administered:
   a. Have appropriate cultures been obtained for a specific microbiologic diagnosis?
   b. Has the patient received this drug or related compounds previously? If so, did the patient tolerate the drug? Were there any signs of toxicity or sensitization?
   c. Does the patient have a condition that requires exclusion of some drugs? For example, children with glucose-6-phosphate dehydrogenase deficiency may have induced hemolysis when a sulfonamide, nitrofurantoin, or primaquine is administered.
2. Factors to be considered when writing orders for the administration of antimicrobial agents in a hospital:
   a. If the drug is given by mouth, will coadministration with food interfere with absorption, or is diarrhea a risk?
   b. If a parenteral route is used, should the drug be administered by the intravenous or the intramuscular route?
   c. If the drug is administered by the intravenous route, is push, steady drip, or continuous drip preferred?
   d. Should the drug be instilled directly at the site of infection?
   e. Will the drug diffuse to the site of infection?
   f. Should incision and drainage of the infected area be performed before or after beginning therapy? Incision and drainage should be considered whenever a significant collection of pus is present. If a drainage procedure is performed, material should be obtained for culture and susceptibility testing.
   g. Does the patient have renal or hepatic insufficiency that requires alteration of the dosage schedule?
   h. Are any special precautions required for household contacts? Prophylaxis may be warranted in special circumstances of infection occurring in the household, daycare center, or nursery school.

3. Use of antimicrobial agents in children who are treated as outpatients:
   a. Have the names and functions of the drugs been communicated to the patient and the parent? Do any of the drugs prescribed interact with each other?
   b. Is the dosage schedule simple and satisfactory for the family circumstances (e.g., the child's school schedule or the schedule of the working parents)?
   c. Does the child have an adequate supply of the drug until it can be purchased? If not, the use of starter packages is of value. Administration of the first dose in the clinic is advantageous because it provides knowledge of acceptance and tolerability of the drug by the child.
   d. Are parents given instructions for reporting the clinical course by telephone? Is an appointment made for the next visit?
   e. Does the patient or parent know how to assess adequacy of response to the drug? Does the parent know how to take the child's temperature?
   f. Is the total amount of drug prescribed adequate for the course? Will refills of the prescription be needed?
   g. Is the drug provided in a convenient dosage form? Will the package be provided with an adequate means of measuring the drug? Does the agent require refrigeration?
   h. Has the patient or parent been informed of signs of side effects or toxicity?
   i. Are generic equivalents of the drug adequate?
   j. Will the patient be able to pay for the drug if it is purchased elsewhere (away from the clinic)? If applicable, will a third party pay for this prescription? (In some states, prescriptions by brand name may not be filled because reimbursement by the third-party payer, such as Medicaid, is insufficient.)
4. After the patient's course:
   a. How long should the patient take the drug?
   b. When should the initial choice of antimicrobial agents be reconsidered? When the results of cultures and appropriate susceptibility tests are available, should the initial choice be reevaluated and altered, if necessary?
   c. What studies should be performed to monitor the safety and adequacy of the regimen? Hematologic indices must be measured during the administration of certain antibiotics to detect any adverse reaction. Vigilance is important to detect symptoms or signs attributable to adverse reactions.
   d. Are repeat cultures necessary? In certain cases, the most appropriate criterion of efficacy is evaluation of the results of cultures.
   e. What clinical and laboratory signs of efficacy should be monitored? Signs may differ for different diseases and various drugs but should be considered by the physician when the course of therapy is designed.

TABLE 235-14 Factors Contributing to Antimicrobial Failure

Host Related
Foreign body present
Anatomic defect
Defect in immune response to infection
Poor absorption of enteral antibiotic
Disease Related
Antibiotic inappropriate for the disease
Ancillary therapy not instituted (e.g., surgical drainage)
Sequestered focus of infection (undetected or inaccessible)
Organism Related
Acquired resistance to an antimicrobial agent
Superinfection with resistant bacteria
Drug Related
Inadequate adherence
Improper dosage schedule: route, dose, or duration
Inadequate diffusion to the site of infection
Drug–drug interactions: antibiotic inactivation or antagonism
Deterioration of drug during storage

5. What factors should be considered if the patient fails to respond to the antimicrobial agent? If the patient does not respond appropriately to the course of therapy, various factors must be considered, including those related to the disease, host, drug, or organism (Table 235-14).
6. What steps can be taken to prevent reinfection? For example, in certain circumstances prophylactic antibiotics, immunizations, or surgical procedures may be warranted.

CHAPTER 236

Antimicrobial Prophylaxis

Gary D. Overturf

Antimicrobial prophylaxis is the limited administration of an antimicrobial agent or agents before or immediately after exposure to an infectious agent, with the intent of preventing an infection. Prevention is always preferred, provided the means are available and the risk-benefit and cost-benefit ratios are acceptable. The focus of this chapter is on the prevention of morbidity and mortality from bacterial infections through the prophylactic, and often the empirical, use of antimicrobial agents. For many prophylactic regimens, their employment is justified on the severity of the disease; and in many instances, an evidence base supporting their use is meager or nonexistent, whereas for other regimens, such as those employed in surgery, substantial evidence of their efficacy exists for recommended regimens. Prophylaxis against viral infections such as human immunodeficiency virus and varicella, among others, will not be discussed but rather only prophylaxis against bacterial infections and some fungal (yeast) infections is addressed. For discussions of available prophylaxis against viral infections, please consult the chapters addressing specific viral agents.

GENERAL PRINCIPLES OF PROPHYLAXIS

Factors that influence the efficacy of prophylactic regimens are related to the potential pathogen, the prophylactic agent, the host, and the disease to be prevented (Table 236-1). In addition, the pharmacology, pharmacodynamics, and pharmacokinetics of the antimicrobial agents will affect the efficacy of prophylaxis and dictate the dosage and the timing of the administrations of the antibiotics and the duration of use. Failure to consider these factors will often lead to ineffective prophylaxis, overuse of antimicrobial agents, promotion of resistant microorganisms, economic waste, and risk for development of toxicity or other significant side effects.

The Bacterial Pathogen

Prophylaxis is theoretically more effective when a single pathogen is targeted. In general, the greater the number of targeted pathogens, the less effective, the more toxic, and the more expensive the regimen becomes. Ideally, prophylaxis should be administered at the time of exposure to the potential pathogen. If exposure is prolonged or continuous, prophylaxis becomes less effective and less desirable. Bacteria that are not endogenous to the host (i.e., not part of the host's normal flora) generally are targeted more effectively if the exposure is known and identified.

The Disease

The severity of the disease to be prevented is a major consideration. Potentially fatal infections such as meningococcemia or infections that result in high morbidity such as endocarditis or infections of surgically implanted devices are justifiably targeted. Prophylaxis usually is not required for minor illnesses (e.g., cuts, abrasions). The site of infection also is important. Adequate concentrations of antimicrobial agents are achieved readily in organs that are highly vascular and have no anatomic barriers, whereas infections in restricted anatomic compartments (e.g., middle ear) or those that involve prosthetic materials may require special consideration.

The Antimicrobial Agent

The most desirable prophylactic regimen is one in which a single, inexpensive antimicrobial drug is utilized with a narrow spectrum, which is easily administered and well tolerated with minimal side effects. The less frequently an agent is given, the more reliable the compliance of the patient to the prophylactic regimen.[74] When prophylaxis can be achieved effectively with a single administration of the antimicrobial agent, prophylaxis is likely to approach the ideal.

PROPHYLAXIS IN NEONATES

Ophthalmia Neonatorum

Prophylaxis recommendations target *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Ideally, prophylaxis should be directed at infants who are exposed to these two pathogens, but routine mass identification of such groups with certainty is problematic. Although routine prophylaxis has been discontinued in some countries (United Kingdom, Sweden),[37] topical antibiotic prophylaxis for ophthalmia neonatorum for these two agents continues to be recommended in the United States.[35,36]

In the past, topical 1 percent silver nitrate solutions, available in single-dose ampules, was the standard prophylaxis and tetracycline ophthalmic preparations were considered the alternative. Neither tetracycline nor silver nitrate is produced in the United States, whereas single-dose tubes of an ophthalmic ointment containing 0.5

Cost, toxicity, side effects, and acceptability of the agent
Likelihood and consequences of emerging resistance

percent erythromycin are provided. All three agents are effective prophylaxis for gonococcal ophthalmia neonatorum.[68] However, because silver nitrate frequently causes chemical conjunctivitis its use has been largely discontinued in most countries. Erythromycin and tetracycline ophthalmic ointments appear to be as effective as silver nitrate solution for routine prophylaxis of gonococcal ophthalmia,[87,139] but silver nitrate probably is the most reliably effective agent against penicillinase-producing *N. gonorrhoeae*. The effectiveness of erythromycin or tetracycline in the prevention of ophthalmia caused by penicillinase-producing *N. gonorrhoeae* has not been established. No topical regimen has proven efficacy against *Chlamydia* conjunctivitis or prevention of invasive *Chlamydia* infections of the neonate, such as lower respiratory tract infection.[18,38,69] Furthermore, topical regimens do not eliminate *C. trachomatis* from the nasopharynx and do not prevent pneumonia.

Prophylaxis should be administered as soon as possible after birth. Each eyelid should be wiped gently with sterile cotton before local prophylaxis is administered. Care must be exercised to ensure that the solution or ointment is in the conjunctival sac and that it is not flushed from the eye after instillation. Administration of ophthalmic prophylaxis is the law in most states. Most importantly, prophylaxis against *Chlamydia trachomatis* or gonorrhea infection should be provided if identified in pregnant women before delivery during routine screening. Appropriate regimens of ceftriaxone (25 to 50 mg/kg intramuscularly or intravenously not to exceed 125 mg in a single dose) for maternal infections with gonorrhea or chlamydia (azithromycin 1.0 g orally or alternative regimens of ampicillin or erythromycin) are reviewed in the periodic updates of the Centers for Disease Control and Prevention (CDC) sexually transmitted disease treatment guidelines.[35,36]

Group B Streptococcal Infections

Prophylaxis is recommended for the prevention of early-onset (onset within the first week of life) neonatal group B streptococcal infections.* No recommendations for prophylaxis against late-onset infections exist. The current indications for treatment of neonates and maternal carriers or those mothers at risk for transmission of group B streptococcal infections to their infants is reviewed in Chapter 83 and available from the CDC[34] and the American Academy of Pediatrics.[5]

Multiple regimens have been evaluated to reduce vertical transmission of group B streptococcus.[1] The antepartum use of oral antimicrobial agents to eradicate group B streptococcus colonization of mothers (antepartum chemoprophylaxis) have not been successful, even when sexual partners were treated concurrently.[105] Prophylaxis of neonates with penicillin G or ampicillin soon after birth (postnatal chemoprophylaxis) is ineffective in preventing early-onset group B streptococcal disease, primarily because in most patients infection occurs in utero and the infants are asymptomatic at or within a few hours after birth.

Therefore, current recommendations focus on treatment of all colonized women identified by recommended universal testing at 35 to 37 weeks' gestation.[5,34] American Academy of Pediatrics recommendations and CDC guidelines recommend that lower vaginal and anorectal (single swab) specimens for culture be obtained at 35 to 37 weeks' gestation, placed into selective broth medium, transported, and subcultured onto solid media.[8,32] Both hybridization assays and DNA amplification techniques for detection of group B streptococci also are available and serve as the only acceptable alternatives to culture.[16,73] Rapid nucleic amplification methods are available for testing women at the time of entry into labor and thus provide opportunities for treatment of women who may not have been tested at 35 to 37 weeks' gestation. Maternal group B streptococcus carriers identified ante partum or those without culture or identification at the time of delivery with rapid testing but with one or more risk factors (see Chapter 83) should be given intrapartum intravenous ampicillin (2 g initially, then 1 g every 4 hours) or penicillin G (5 million U initially, then 2.5 million U every 4 hours until delivery).[32] Penicillin-allergic women may be given clindamycin or erythromycin intravenously. Previous delivery of an infant with invasive group B streptococcal disease warrants intrapartum maternal chemoprophylaxis for each subsequent pregnancy, regardless of maternal colonization.

Intrapartum antibiotic prophylaxis prevents substantial numbers of, but not all, cases of early-onset neonatal group B streptococcal infection[75] and decreases the incidence of maternal group B streptococcal postpartum complications, including endometritis.[90,100] Since the institution of intrapartum antimicrobial prophylaxis, the rate of invasive group B streptococcal disease has declined by greater than 65 percent in prescreened mothers, and administration of intravenous ampicillin reduces the risk for development of early-onset group B streptococcal infection by 36 percent in infants born to women with premature rupture of membranes.[15] However, the decrease in the rate of group B streptococcal disease may been associated with an increased rate of disease caused by gram-negative pathogens.

Necrotizing Enterocolitis

Neonatal necrotizing enterocolitis (NEC) is a multifactorial disease, with bowel wall necrosis of variable length

*References 2, 8, 19, 105, 114, 117.

and depth being the characteristic common feature. Factors including ischemic stress, disruption of the bowel mucosal barrier, and resultant bacterial proliferation and invasion of the intestinal wall are part of the pathogenesis of NEC. Therefore, suppression of gastrointestinal flora with nonabsorbable oral antimicrobial agents has been used in an effort to prevent the development of NEC in premature infants. Administration of oral kanamycin or gentamicin prophylactically in the first few hours of life has resulted in contradictory data. Furthermore, selective overgrowth of resistant organisms in the bowel and significant systemic absorption of aminoglycosides from the injured mucosa are potential risk factors. Therefore, currently, oral aminoglycosides are not recommended for the routine prophylaxis or treatment of NEC. One report[104] suggests that oral vancomycin given for 48 hours before the introduction of oral feeding may be beneficial in preventing NEC. These observations on the use of antibiotics for prevention of NEC have not been confirmed, and such prophylaxis is not recommended. Lastly, orally administered probiotics have been suggested to alter the bowel flora and to reduce the incidence or severity of NEC. For instance, in recent studies, infants fed breast milk and products including *Lactobacillus acidophilus* and *Bifidobacterium infantis* had a reduced occurrence or reduced severity of NEC[92] and a meta-analysis or composite studies have supported the positive effects of probiotics in the prophylaxis against NEC.[82,93]

Intravascular Catheter Insertion

Infection with coagulase-negative staphylococci, primarily *Staphylococcus epidermidis*, is likely to occur in premature infants or infants who have indwelling vascular catheters. Low-grade sepsis is the most common clinical manifestation; however, meningitis, endocarditis, omphalitis, cellulitis, and other focal infections may occur. Two randomized trials of low-dose vancomycin added to total parenteral nutrition fluids (25 μg of vancomycin per milliliter of fluid) suggested that such a prophylactic regimen significantly reduces coagulase-negative staphylococcal infections in small premature infants in neonatal intensive care units.[78,127] Despite the possible effectiveness of vancomycin prophylaxis,[13] the American Academy of Pediatrics has not made a routine recommendation for low-dose vancomycin because of the potential promotion of emerging resistance in gram-positive pathogens. Although continuous administration of fluconazole has been studied in high-risk, low-birth-weight infants who are at risk for development of systemic infections caused by *Candida* spp., the American Academy of Pediatrics currently does not endorse the use of continuous fluconazole as an accepted prophylactic procedure. The recent interest in anti-infective agents such as ethanol as an antibiotic lock solution for treatment and/or elimination of colonization of chronic indwelling lines has been proposed as an acceptable alternative to antibiotics[107,115,122]; however, although these agents have been effective for treatment and/or elimination of potential pathogens in biofilms infecting lines, they remain only recommended for treatment of lines infected with organisms not responsive to recommended treatment.[106]

DISEASE-TARGETED PROPHYLAXIS

Rheumatic Fever

Group A streptococcal infections of the pharynx are the precipitating cause of rheumatic fever. Appropriate antibiotic treatment of streptococcal pharyngitis prevents the development of acute rheumatic fever in most cases.[47] Because at least one third of episodes of acute rheumatic fever result from inapparent streptococcal infections[41] and some symptomatic patients do not seek medical care, not all instances of rheumatic fever are preventable. Prevention of first attacks (primary prevention) is accomplished by proper identification, adequate antibiotic treatment, and eradication of this streptococcal infection. An individual who has suffered an attack of rheumatic fever is at very high risk for recurrence after subsequent group A streptococcal pharyngitis and needs continuous chemoprophylaxis to prevent such recurrence (secondary prevention).[43] The prophylaxis of rheumatic fever also is discussed in Chapter 29.

Primary Prevention

The primary treatment of episodic recurrent group A streptococcal infections is important in the prevention of rheumatic fever and recurrent episodes. The diagnosis and treatment of group A streptococcal infections are discussed in Chapter 82, and the prevention of rheumatic fever and its prophylaxis are discussed in Chapter 29. The acceptable regimens for treatment of acute group A streptococcal infections[4,10,62,136] are provided in Table 236-2. Even when treatment is started as long as 9 days after the onset of acute illness, penicillin may effectively prevent primary attacks of rheumatic fever.[30] Therefore, a brief delay (24 to 48 hours) for processing of the throat culture before initiation of antibiotic therapy does not increase the risk for development of rheumatic fever. However, therapy also shortens the duration of clinical symptoms, so initiation of therapy at the earliest possible time is favored.[14] Intramuscular benzathine penicillin G is preferred to oral penicillin, particularly for patients who are unlikely to complete a 10-day course of oral therapy and for patients with a personal or family history of rheumatic fever, rheumatic heart disease, or other factors that place them at substantial risk for development of rheumatic fever.[43]

Secondary Prevention

Continuous antibiotic administration is indicated in patients at risk for developing or recurrent disease after having infection with group A streptococcus or for those children with congenital or acquired cardiac disease who are at risk for development of endocarditis. Both the American Academy of Pediatrics and the American College of Cardiology provide recommendations for prophylaxis.

An individual in whom streptococcal pharyngitis develops after a previous attack of rheumatic fever is at high risk for having a recurrent attack of rheumatic fever, even after those infections that are asymptomatic or in

TABLE 236-2 **Prevention of Rheumatic Fever**

Agent	Dose	Mode	Duration
Primary Prevention			
Benzathine penicillin G	600,000 units for patients ≤27 kg 1.2 million units for patients >27 kg	Intramuscularly	Once
Penicillin V	Children: 250 mg 2-3 times daily (<60 lb) Children ≥ 60 lb or adults: 500 mg 2-3 times daily	Orally	10 days
For Individuals Allergic to Penicillin			
Erythromycin (Azithromycin for 5 days may be substituted; see package insert for dosage)	40 mg/kg/day divided 2-4 times daily (1 g maximum/day	Orally	10 days
Secondary Prevention			
Benzathine penicillin G	1.2 million units every 3-4 wk	Intramuscularly	See text
	or		
Penicillin V	250 mg twice daily	Orally	See text
	or		
Sulfadiazine	0.5 g once daily for patients ≤27 kg (60 lb) 1 g once daily for patients >27 kg (60 lb)	Orally	See text
For Individuals Allergic to Penicillin and Sulfadiazine			
Erythromycin	250 mg twice daily	Orally	See text

*Clarithromycin for 10 days or azithromycin for 5 days in recommended doses is also effective.
From Dajani A, Taubert K, Ferrieri P, et al. Treatment of acute streptococcal pharyngitis and prevention of rheumatic fever: a statement for health professionals. *Pediatrics* 1995;**96**:758-764. Copyright 1995, American Academy of Pediatrics.

those symptomatic infections that are treated optimally. Therefore, prevention of recurrent rheumatic fever requires continuous antimicrobial prophylaxis rather than recognition and treatment of acute episodes of streptococcal pharyngitis.[43] Continuous prophylaxis is recommended for patients with a well-documented history of rheumatic fever (including cases manifested solely by Sydenham chorea) and for those with definite evidence of rheumatic heart disease. Such prophylaxis should be initiated as soon as acute rheumatic fever or rheumatic heart disease is diagnosed. A full therapeutic course of penicillin or other effective regimen should be given first to patients with acute rheumatic fever to eradicate residual group A streptococcus, even if a throat culture is negative at that time. Streptococcal infections occurring in family members of patients with rheumatic fever should be treated promptly.

An injection of 1.2 million units of benzathine penicillin G for patients weighing less than 27.3 kg (60 lb) every 4 weeks is the recommended regimen for secondary prevention in most circumstances in the United States (see Table 236-2). In countries where the incidence of rheumatic fever is particularly high, in special circumstances, or in certain high-risk individuals, such as patients with residual rheumatic carditis, administration of benzathine penicillin G every 3 weeks is justified and recommended.[94,95] Long-acting penicillin is of particular value in patients with a high risk for having a recurrence of rheumatic fever, especially those with rheumatic heart disease, in whom recurrence is very serious. The advantages of giving benzathine penicillin G must be weighed against the inconvenience to the patient and the pain of injection, which causes some individuals to discontinue prophylaxis.

Successful oral prophylaxis (penicillin V or sulfadiazine, see Table 236-2) depends primarily on the patient's adherence to prescribed regimens.[42] Patients need to be given careful and repeated instructions about the importance of prophylaxis. Most failures of prophylaxis occur in nonadherent patients. Even with optimal adherence of the patient, the risk for having a recurrence is higher in individuals receiving oral prophylaxis than in those receiving intramuscular benzathine penicillin G.[56] Oral agents are more appropriate for patients at lower risk for having rheumatic recurrence. Accordingly, some physicians elect to switch therapy to oral prophylaxis when patients have reached late adolescence or young adulthood and have remained free of rheumatic attacks for at least 5 years.

Duration of appropriate prophylaxis has been defined for those with rheumatic fever without carditis for 5 years after the last episode or until 21 years of age, whichever is longer, whereas for those with carditis prophylaxis should be at least 10 years or until age 21, whichever is longer.[17] For those with residual heart disease (e.g., persistent valvular disease), prophylaxis should be given at least 10 years after the last episode or until age 40 years, whichever is longer.[4,62]

Although sulfonamides are not effective in the eradication of group A streptococcus, they do prevent development of infection. Sulfonamide prophylaxis is contraindicated in late pregnancy because of transplacental passage of such drugs and potential competition with bilirubin for albumin-binding sites.

For patients who are allergic to penicillin and sulfisoxazole, erythromycin or other macrolide (e.g., azithromycin or clarithromycin) is recommended. No data have been published about the use of other penicillins, macrolides, or cephalosporins for the secondary prevention of rheumatic fever, but the American Academy of Pediatrics has stated that clarithromycin for 10 days or azithromycin for 5 days is adequate for treatment.

Bacterial Endocarditis

In 2007,[136] and again in 2008,[135] recommendations for antimicrobial prophylaxis were changed significantly from 1997 guidelines.[44] The rationale for these changes included three central concepts. First, endocarditis is much more likely to result from frequent exposure to random bacteremias associated with daily activities than from bacteremia caused by a dental, gastrointestinal tract, or genitourinary procedure. Second, prophylaxis may prevent an exceedingly small number of (if any) cases of endocarditis in individuals who undergo any procedure and the risk for adverse reactions to antibiotics probably exceeds the benefit in any form of prophylactic treatment. Third, maintenance of optimal oral health and hygiene may reduce the incidence of bacteremia from daily activities and is more important than prophylactic antibiotics for a dental procedure to reduce the risk for endocarditis.

Therefore, recommendations for the use of antibiotic prophylaxis after 2007 were limited to the highest risk cardiac conditions. Cardiac conditions associated with the highest risk are listed in Table 236-3. Prophylaxis is no longer provided to all subjects who have the highest lifetime risk for endocarditis. For patients with high-risk conditions listed in Table 236-3, all dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa are reasonable for administration of dental prophylaxis. Events and procedures such as routine anesthetic injections through noninfected tissues, taking dental radiographs, placement or removal of prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa do not require prophylaxis. The recommendations for regimens for oral and parenteral antibiotics listed in Table 236-4 are for all dental procedures for which dental prophylaxis is reasonable for persons with high-risk conditions.

Recommendations for antimicrobial prophylaxis for respiratory procedures are only for procedures that involve the incision or incisional biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy. Therefore, prophylaxis is not recommended for bronchoscopy unless an incision of the respiratory tract will be made. An antimicrobial regimen that includes coverage of viridans group streptococci[25] can be selected from Table 236-4.

When using prophylaxis for high-risk procedures of the gastrointestinal or genitourinary tract, consideration

TABLE 236-3 Cardiac Conditions Associated with the Highest Risk for Adverse Outcomes from Endocarditis for Which Prophylaxis with Dental Procedures is Reasonable

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- A history of previous infectious endocarditis
- Congenital heart disease (CHD)
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device inserted by surgery or catheter intervention during the first 6 months after the procedure
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop valvulopathy

TABLE 236-4 Prophylactic Antimicrobial Regimens for Dental Procedures

		Regimen, Single Dose 30-60 Minutes Before Procedure	
Situation	**Agent**	**Adults**	**Children**
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medications	Ampicillin	2 g IV or IM	50 mg/kg IV or IM
	or		
	Cefazolin or ceftriaxone	1 g IV or IM	50 mg/kg IV or IM
Allergic to penicillins or ampicillin—oral	Cephalexin	2 g	50 mg/kg
	or		
	Clindamycin	600 mg	20 mg/kg
	or		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medications	Cefazolin or ceftriaxone	1 g IV or IM	50 mg/kg IV or IM
	or		
	Clindamycin	600 mg IV or IM	20 mg/kg IV or IM

IM, intramuscularly; IV, intravenously.

of the possible involvement of enterococcal organisms must be considered as well as the inclusion of mixed infections with aerobic and anaerobic gram-negative and gram-positive organisms.[15,52] However, only enterococci are frequent causes of endocarditis. In the revised recommendations of 2007, the administration of prophylactic antibiotics solely to prevent endocarditis is not recommended for patients who undergo esophagogastroduodenoscopy or colonoscopy, which is in contrast to previous recommendations made in 1997. For patients with infections of the gastrointestinal or genitourinary tract who may have intermittent or sustained enterococcal bacteremia or for those who receive antibiotic therapy to prevent wound infection or sepsis associated with a gastrointestinal or genitourinary tract procedure, it is reasonable to include an agent active against enterococci, such as penicillin, ampicillin, piperacillin, or vancomycin. Similarly for patients with high-risk conditions listed in Table 236-3, antibiotic therapy to eradicate the infection from the urine before surgery is reasonable for those who are scheduled for an elective cystoscopy or other urinary tract manipulation who have an enterococcal urinary tract infection or colonization. Amoxicillin or ampicillin is the preferred agent for enterococci, but vancomycin may be used in those intolerant of β-lactam antibiotics.

Incision of surgically scrubbed skin without an underlying or adjacent infection is not likely to cause bacteremia, and prophylaxis is not recommended. In contrast, procedures on infected skin, skin structure, or musculoskeletal tissues are likely to cause endocarditis. Therefore, for children with high-risk cardiac conditions, a therapeutic regimen administered for treatment of the infection should contain an agent active against staphylococci and β-hemolytic streptococci, such as an antistaphylococcal penicillin or cephalosporin. Vancomycin or clindamycin may be administered to children unable to tolerate β-lactam antibiotics or those who are known or suspected to be infected with a methicillin-resistant strain of staphylococcus (MRSA).

The 2007 changes in recommendations for prophylaxis for endocarditis represent substantial changes to all the recommendations before 1997. Therefore, a summary of those recommendations is listed in Table 236-5. In addition, the recommendations to withhold prophylaxis to subjects with a number of conditions have not changed, and those conditions or situations are listed in Table 236-6.

TABLE 236-5 Summary of Changes and New Recommendations for Antibiotic Prophylaxis for Bacterial Endocarditis*

Bacteremia resulting from daily activities is much more likely to cause endocarditis than bacteremia associated with a dental procedure.
Only an extremely small number of cases of endocarditis might be prevented by antibiotic prophylaxis even if prophylaxis were 100% effective.
Prophylaxis is now recommended only for high-risk procedures (see Table 236-3), and prophylaxis is no longer recommended for any other form of congenital heart disease except for those listed in Table 236-4.
Prophylaxis is reasonable only for dental procedures that involve the manipulation of the gingival tissues or periapical region of teeth or perforation of the oral mucosa, and only for those with very high-risk conditions.
Antibiotic prophylaxis is reasonable for procedures on respiratory tract or infected skin or skin structures or musculoskeletal tissues only for patients with underlying cardiac conditions with the highest risk for adverse outcomes from endocarditis.
Antibiotic prophylaxis solely to prevent endocarditis is no longer recommended for genitourinary or gastrointestinal tract procedures.
Conditions previously listed as not requiring prophylaxis (1997) continue to not require prophylaxis and now include vaginal delivery, hysterectomy, and tattooing, although body piercing for patients with high-risk conditions for endocarditis should not be performed.

Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation* 2007;**116**:1736–54.

Recurrent Otitis Media

Acute otitis media is one of the most common infections in infants and children and has a tendency to recur, particularly during the first few years of life. In addition to tympanostomy tube placement and adenoidectomy, antimicrobial prophylaxis is one of the options that may be considered for the management of recurrent otitis media.[29,51,113] Chemoprophylaxis of otitis media is discussed also in Chapter 16. Despite recommendations for the use of prophylaxis in some children with recurrent otitis media, these recommendations remain controversial and without a clear consensus for their effectiveness and safety.

Antimicrobial prophylaxis has been recommended for a child who has had three or more episodes of acute otitis media in 6 months or four episodes within a year, with the last episode occurring during the previous 6 months.[63,109] Patients most likely to benefit from prophylaxis include those younger than 2 years, those in out-of-home childcare, and Native American children.[83,109] Prophylaxis is directed against the most common potential pathogens that cause otitis media: *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and nontypeable *Haemophilus influenzae*. Amoxicillin, at a dose of 20 mg/kg, or sulfisoxazole, at a dose of 50 mg/kg, may be given orally each evening for a period of 3 to 6 months or during the winter months. Although many other antimicrobial agents are used for the treatment of otitis media, only amoxicillin and sulfisoxazole currently are recommended as prophylactic agents because only these two agents have undergone critical analysis in prospective trials. Antimicrobial prophylaxis must be used with great caution and balanced against the potential for increasing the emergence of resistant organisms, particularly *S. pneumoniae*, and the possible occurrence of drug-associated toxicity (e.g., neutropenia, rash, or other). Other measures that may decrease the incidence of recurrent acute otitis

TABLE 236-6 Conditions for Which Antibiotics Should Not Be Used Solely for Endocarditis Prophylaxis

Cardiac Conditions

Isolated secundum atrial septal defects
Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residual and beyond 6 months of age)
Previous coronary artery bypass graft surgery
Mitral valve prolapse without valvular regurgitation
Physiologic, functional, or innocent heart murmurs
Previous Kawasaki disease without valvular dysfunction
Previous rheumatic fever with valvular dysfunction
Cardiac pacemakers (intravascular and epicardial and implanted defibrillators)

Respiratory Tract

Endotracheal intubation
Bronchoscopy with a flexible bronchoscope, with or without biopsy
Tympanostomy tube insertion

Gastrointestinal Tract

Endoscopy with or without gastrointestinal biopsy

Genitourinary Tract

Vaginal hysterectomy
Vaginal delivery
Cesarean section
In uninfected tissue:
- Urethral catheterization
- Uterine dilation and curettage
- Therapeutic abortion
- Sterilization procedures
- Insertion or removal of intrauterine devices

Other

Cardiac catheterization, including balloon angioplasty
Implanted cardiac pacemakers, implanted defibrillators, and coronary stents
Incision or biopsy of surgically scrubbed skin
Circumcision

media include eliminating smoking in the home, reducing daycare attendance, eliminating pacifiers, and administering influenza and the heptavalent conjugated pneumococcal vaccines. If these measures do not prevent recurrent infections, referral to an otolaryngologist is recommended for evaluation and possible tympanostomy tube placement or adenoidectomy, or both procedures.

Recurrent Urinary Tract Infection

Urinary tract infection (UTI) occurs in approximately 5 percent of girls and 1 to 2 percent of boys.[142] Recurrent UTIs are noted in 30 to 50 percent of children with UTIs, with most recurrences taking place within 3 months after the initial episode. Eighty percent of recurrences are new infections caused by different colonic bacterial species that have become resistant to recently administered antibiotics. The recurrence rate is not altered by extending the duration of treatment.

Renal parenchymal infections and renal scarring are well-recognized complications of UTIs in children.[72,99,123] Parenchymal scarring is found in 10 to 15 percent of children with UTIs,[126,142] hypertension will develop in an estimated 10 percent of children with this complication, and renal insufficiency may develop in a smaller number.[76] Vesicoureteral reflux is noted in 30 to 50 percent of children with UTIs,[99] the frequency being related directly to the number of UTI episodes and inversely to age. Children with reflux have a much higher incidence (30% to 60%) of pyelonephritic scarring than do children without reflux. More than 90 percent of children with renal parenchymal scarring have had vesicoureteral reflux and a history of UTI.[126,142]

Children who have three or more UTIs in a 12-month period may benefit from suppressive antibiotic therapy for as long as 6 months to allow repair of intrinsic bladder defense mechanisms.[142] In children with anatomic defects or reflux, suppressive therapy may be needed for as long as the underlying defect exists.

Appropriate prophylactic agents should result in low serum but high urinary levels of the medication, have minimal effect on fecal flora, be well tolerated, and be inexpensive.[98] Methenamine mandelate (75 mg/kg divided every 12 hours) is a suitable agent for prophylaxis because it releases formaldehyde in an acid medium. A pH of 5.5 or lower must be maintained in the urine to obtain optimal results. Ascorbic acid or other acidifying agents should be used to achieve the desired urine acidity. Other useful agents for prophylaxis in children with normal renal function are trimethoprim-sulfamethoxazole (TMP-SMX), nitrofurantoin, and nalidixic acid.[23,55,70,99,120] TMP-SMX can be given at 2 mg of TMP and 10 mg of SMX per kilogram in a single daily dose or at 5 mg of TMP and 25 mg of SMX per kilogram twice a week. TMP has the additional unique characteristic of diffusing into vaginal and urethral fluids, thereby decreasing bacterial colonization with members of the Enterobacteriaceae and diminishing ascending reinfection.[70,128] Nitrofurantoin is recommended at 1 to 2 mg/kg, taken each night. It has been used effectively as prophylaxis for recurrent UTIs in infants and children. Pulmonary, neurologic, and hepatic adverse effects have been reported but are rare occurrences.[99] Nalidixic acid (not recommended for children younger than 3 months) is administered at 30 mg/kg divided every 12 hours. It is a bactericidal agent for most of the common gram-negative uropathogens. More recently, various cephalosporins and amoxicillin–clavulanic acid have been used as prophylactic agents with good results.[98] Prophylactic agents are best administered as a single dose at bedtime.

Prophylaxis for UTIs may reduce the incidence of UTIs by up to 50 percent in children with nocturnal continence. No studies of prophylaxis in children without nocturnal continence have shown efficacy, and prophylactic regimens employing broad-spectrum antibiotics (e.g., amoxicillin, cephalexin) are associated with the emergence of recurrent infections caused by antibiotic-resistant organisms such as *Pseudomonas aeruginosa*.

POSTEXPOSURE PROPHYLAXIS

Prophylaxis targeted against specific organisms after an individual is exposed is discussed in this section.

Pertussis

Prompt administration of erythromycin or other approved macrolide drug to those in close contact with a case of pertussis is effective in limiting secondary transmission. Close contacts are household members, attendees of childcare facilities, and other individuals who are in contact with the index infected individual for 4 hours or more a day. Chemoprophylaxis is recommended irrespective of age or vaccination status because immunity after receiving pertussis immunization is not absolute and may not prevent development of infection.[2] The recommended dose of erythromycin is 40 to 50 mg/kg/day (maximum, 2 g/day) to be given orally in four divided doses for 14 days. Both clarithromycin, 15 mg/kg, up to a maximum of 1.0 g, divided twice daily for 7 days, and azithromycin at standard doses (10 mg/kg the first day, up to a maximum of 500 mg, followed by 5 mg/kg, up to a maximum of 250 mg, each of the days 2 through 5) have been shown to be as effective as erythromycin and are much better tolerated than is erythromycin.[33] Individuals who are allergic to erythromycin or macrolides or those who cannot tolerate their side effects may be given TMP-SMX, although the efficacy of this regimen has not been documented. The dose is 8 mg/kg/day (TMP) and 40 mg/kg/day (SMX) orally in two divided doses for 14 days.[33]

Persons who have been in contact with an infected individual should be monitored closely for respiratory symptoms for 2 weeks after the last contact. The risk for contracting pertussis in adults providing medical care to children should be recognized. Symptoms may be mild and not readily recognized as pertussis; however, such individuals can transmit the infection.

Meningococcal Infections

Close contacts of patients with invasive disease caused by *Neisseria meningitidis* (meningococcemia, meningitis, or both) are at higher risk for acquisition of infection than is the general population. Secondary cases and outbreaks may occur in households, childcare centers, nursery schools, colleges, and military camps.[2] The attack rate for household contacts is 0.3 to 1.0 percent (300 to 1000 times the rate in the general population). Spread from patients to medical care providers occurs infrequently unless intimate contact (e.g., mouth-to-mouth resuscitation, intubation, suctioning) occurs. Respiratory tract cultures are not recommended and are not of value in deciding who should receive prophylaxis.[2]

Chemoprophylaxis should be administered as soon as possible, preferably within 24 hours of identification of the index case.[2] Treatment with penicillin G, ampicillin, or sulfonamides for meningococcal disease does not eradicate nasopharyngeal carriage of *N. meningitidis* reliably, whereas treatment with extended-spectrum cephalosporins (e.g., ceftriaxone and cefotaxime) does eliminate carriage. Therefore, antimicrobial chemoprophylaxis should be administered to the index patient before discharge from the hospital if the patient has been treated with the first three antibiotics.

The antibiotic of choice in most instances is rifampin. The recommended regimen is 10 mg/kg (maximum, 600 mg) every 12 hours for a total of four doses in 2 days. A liquid preparation can be formulated, or the powder can be mixed with applesauce or a similar vehicle. The rifampin prophylaxis regimen recommended for *Haemophilus influenzae* type b disease (see later) also is effective for meningococcal prophylaxis.

Rifampin prophylaxis has several shortcomings.[118] It fails to eradicate *N. meningitidis* in 10 to 20 percent of pharyngeal carriers.[102] It is not recommended for pregnant women. Side effects occur frequently and include headache, dizziness, gastrointestinal symptoms, discoloration of body secretions (saliva, tears, urine), staining of contact lenses, and hepatotoxicity. Finally, several studies have documented the emergence of resistant meningococcal strains after the administration of rifampin prophylaxis.[118]

If the meningococcal isolate is known to be susceptible to sulfonamides, sulfisoxazole may be recommended, but currently it is difficult to obtain. The dose is 500 mg/day for infants, 500 mg every 12 hours for children 1 to 12 years of age, and 1 g every 12 hours for children older than 12 years and adults. The duration of prophylaxis is 2 days.

During an outbreak, a single intramuscular injection of ceftriaxone was significantly more effective than rifampin in eradicating meningococci at 1 week (97% vs. 75%) and at 2 weeks (97% vs. 81%) after prophylaxis.[118] Ceftriaxone administered as a single intramuscular dose (125 mg for children younger than 15 years and 250 mg for adults) now is recommended as an acceptable alternative for prophylaxis. Ceftriaxone has the advantages of ease of administration, possibly greater efficacy, and safety in pregnancy. For high-risk contacts 18 years of age or older, a single 500-mg oral dose of ciprofloxacin is a third option for meningococcal prophylaxis.

Haemophilus Influenzae Type B Infections

The risk for development of secondary invasive disease with *H. influenzae* type b is age dependent.[12] The risk incidence of disease has declined dramatically with the routine use of *Haemophilus* conjugate vaccines. However, in the era when *H. influenzae* type b infections occurred frequently, household contacts younger than 1 year old had the highest risk (6%) for acquisition of secondary illness; the risk in children 4 years old or younger also was high (2.1%). Children older than age 6 years and adults are at little or no risk. The risk for children attending childcare centers may be increased but appears to be less than that for household contacts.[25,57,97,103,108] Exposed hospital personnel do not require antimicrobial prophylaxis. Data on the risk for spread with invasive disease due to other *Haemophilus* serotypes other than b, such as a or f, are unknown, and currently prophylaxis is not recommended for serotypes other than type b.

In addition to protecting vaccinated children against invasive disease, conjugate vaccines appear to decrease pharyngeal colonization, which further reduces *H.*

influenzae type b transmission to unvaccinated children. Prophylaxis currently is recommended for all household contacts, regardless of age, if at least one of the contacts is younger than 4 years and not immunized completely.[2] Complete immunization is defined as having received a conjugate vaccine: (1) at least one dose at 15 months or older, (2) two doses between 12 and 14 months of age, or (3) two or more doses before 12 months of age with a booster at 12 months or older.

Prophylaxis for nursery and daycare center contacts is less well defined, and definitive recommendations are lacking. In general, prophylaxis is recommended for childcare centers with the same regimen as that recommended for households if (1) the center is attended by unvaccinated or incompletely vaccinated children younger than 2 years of age where contact is 25 hours per week or more or (2) two or more cases of invasive *H. influenzae* type b disease occur among attendees within 60 days and unvaccinated or incompletely vaccinated children attend the facility.[2] In facilities where all contacts are older than 2 years or age, prophylaxis need not be given, regardless of vaccination status.

Rifampin in a single dose of 20 mg/kg/day (maximum, 600 mg) for 4 days effectively eliminates oropharyngeal carriage of *H. influenzae* type b in 95 percent of treated individuals.[2] This regimen has been shown to be effective in preventing secondary cases of invasive *H. influenzae* type b disease in household members, daycare settings, and classroom contacts.[12,25] Prophylaxis should be initiated as soon as possible because most secondary cases occur during the first week after identification of the index case.[12] The index patient also should receive rifampin prophylaxis, usually initiated during hospitalization and just before discharge.

If prophylaxis is given to limit secondary spread to a cohort (household or daycare), children vaccinated with any *H. influenzae* type b vaccine and unvaccinated susceptible children should receive prophylaxis.[2] Prophylaxis is not recommended for pregnant women.

Tuberculosis

The three goals of preventive therapy for tuberculosis are (1) to prevent asymptomatic (latent) infection from progressing to clinical (active) disease, (2) to prevent recurrence of past disease, and (3) to prevent initial infection post exposure to persons with active disease in individuals who have negative tuberculin skin test results. The first two goals are covered in detail elsewhere (see Chapter 96); prevention of initial infection post exposure is addressed here. Chemoprophylaxis is given in an attempt to prevent the establishment of infection, and the recipient is protected only as long as antituberculous therapy is continued.

In the United States, isoniazid administered for 9 months is the preferred drug for children for chemoprophylaxis against *Mycobacterium tuberculosis*, for susceptible children exposed to active tuberculosis, or for those with positive reactive skin tests or interferon-γ release assay (LTBI, latent tuberculosis infection). The recommended daily dose of INH is 10 to 15 mg/kg/day (maximum, 300 mg/day) to be given as a single dose. However, alternative regimens, including a 6-month regimen or daily or weekly isoniazid, are recommended for children who cannot comply with a 9-month regimen. For both the 9- and 6-month regimens, twice-weekly, directly observed therapy regimens are equal in efficacy to the daily regimens. Similarly, a daily or biweekly regimen of rifampin-pyrazinamide given for 2 weeks or rifampin given daily is recommended for children exposed to individuals with isoniazid-resistant isolates.[31]

Approximately 9 percent of isolates in the United States are resistant to isoniazid. However, most experts still recommend isoniazid to treat children exposed or reactive (LTBI), unless there is contact with a person with known isoniazid-resistant tuberculosis. If the source case is found to be have an isoniazid-resistant, rifampin-susceptible organism, isoniazid should be discontinued and rifampin (10 to 20 mg/kg, 600 mg maximum) should be given for a total of 6 months.[6] For those exposed to multidrug-resistant tuberculosis strains (defined as resistance to isoniazid and rifampin), neither the ideal regimen nor duration is known; however, drugs to consider include pyrazinamide, fluoroquinolones, and ethambutol depending on the susceptibility of the isolate, and individual consultation with a specialist in the treatment of tuberculosis is advisable.

Persons exposed to an infectious case of tuberculosis should undergo tuberculin skin testing, have a chest radiograph, and receive isoniazid prophylaxis or another appropriate and approved regimen as recommended earlier. If the tuberculin test result is negative and the chest radiograph is normal and the individual is not anergic, isoniazid or another appropriate regimen should be administered for 12 weeks and contact with the index patient should be broken. Isoniazid may be discontinued if the result of a repeated skin test or interferon-γ release assay after 12 weeks of prophylaxis remains negative. If the skin test result becomes positive, isoniazid is continued for a total of 9 months. Candidates for postexposure prophylaxis include persons with impaired immunity; household contacts, particularly children younger than 4 years old; recent contacts, especially human immunodeficiency virus–positive contacts; and persons known to be anergic from populations with a high prevalence of tuberculosis.

Management of a neonate whose mother or other household contact has tuberculosis should be based on individual considerations. In the case of an infant born to a mother (or where a household contact is present) when the chest radiograph is negative but the mother or contact has a positive tuberculin skin test or interferon-γ release assay, the mother and/or contact are candidates for treatment of latent tuberculosis infection, but the infant needs no special evaluation or therapy and the infant can breast-feed. If the mother or a household contact has suspected or active tuberculosis disease, this infection should be reported to the health department and appropriate therapy should be started immediately. If the mother has active disease, the infant should be evaluated for congenital infection and the infant should be separated from the mother and/or contact or until the mother or household contact is wearing a mask and receiving treatment. Once the infant is receiving isoniazid prophylaxis, separation is no longer necessary. Once the mother has received effective therapy, for at least 2 weeks, she may breast-feed the infant.[6]

HOST-TARGETED PROPHYLAXIS

Human and Animal Bites

Human and animal bites are relatively common occurrences. According to the CDC, more than 4.7 million animal bites occur annually in the United States and account for approximately 1 percent of pediatric emergency visits of all such visits.[5,119,133] Dog bites account for 80 to 90 percent of animal bites that require medical care.[24] The organisms most frequently isolated in human bites are *S. aureus*, γ-hemolytic streptococci, *Bacteroides* spp., *Eikenella corrodens*, and *Fusobacterium* spp.[129] In animal bites, *Pasteurella multocida*, *S. aureus*, and anaerobic cocci are the main pathogens.[130]

Data on the use of prophylactic antimicrobial agents after bites are sparse, and the role of prophylaxis in patients who seek medical care early for bite wounds is uncertain.[11,49,119,125] However, because these wounds usually are contaminated with potential pathogens, the administration of prophylaxis should be considered for patients who have the following risk factors: moderate or severe bite wounds, especially with edema or crush injury; puncture wounds, especially if there is penetration of bone, tendon sheath, or joints; a facial, hand or foot, or genital area bite; wounds in immunocompromised and asplenic children; or wounds with delayed presentation with signs of infection (e.g., delay of 18 hours or more between the time of injury and the time of initial physician assessment).* For many of these indications, the use of antibiotics is in effect early treatment rather than prophylaxis because contamination of the wound occurs at the time of the bite.

Because most human and animal bites result in polymicrobial aerobic and anaerobic infections, prophylaxis should target these organisms. For initial prophylaxis, amoxicillin-clavulanic acid (30 to 50 mg/kg/day) probably is optimal therapy.[20,24,55,125] Prophylaxis is recommended for 3 to 5 days. For children with penicillin allergy, an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin has been recommended.[7] Although they are only moderately active against *P. multocida*, erythromycin 30 to 50 mg/kg/day and standard doses of clarithromycin or azithromycin are accepted alternatives in penicillin-allergic children, specifically when these agents are isolated. Other experts recommend clindamycin 30 mg/kg/day divided into three doses as an alternative in children allergic to penicillins or cephalosporins, as noted previously.

Asplenia

The spleen constitutes approximately 25 percent of the lymphoid mass. It filters blood at a rate of 150 mL/min and plays an important role in the primary defense against bacteria that gain access to the circulation.[131] The spleen has an active role in phagocytosis, is a major source of T lymphocytes, and produces immunoglobulin M antibodies, complement, opsonins, and tuftsin (a phagocytosis-promoting tetrapeptide).

Asplenia may be congenital or acquired. In the past, splenectomy was performed frequently and for a variety of indications; currently, a number of methods are available for splenic salvage after trauma. Overwhelming and often fatal septicemia and meningitis occur with increased frequency in asplenic individuals.[141] The frequency of sepsis is 60 times greater in children who undergo splenectomy than in normal children. The risk for sepsis or severe outcome from sepsis is greater in children who lose splenic function by disease or trauma before 2 years of age or in those who have congenital absence of the spleen. Numerous congenital cardiac conditions carry high risk for development of congenital asplenia. Fatality from sepsis in splenectomized individuals is 200 times more common than that in the normal population.[131] The risk for development of sepsis is greatest in patients who have undergone splenectomies for underlying immunologic or reticuloendothelial disorders, and the risk is lowest in children after splenectomy for trauma.[84] In all categories, the risk is highest in young infants and children, but it extends to teenagers and adults as well. The period of heightened susceptibility to infection is the initial 1 to 2 years after splenectomy; however, fulminant infection has been reported as long as 25 years after splenectomy.

S. pneumoniae is the most common cause of septicemia in splenectomized individuals. Despite prompt diagnosis and treatment, pneumococcal septicemia is associated with a fatality rate as high as 50 percent. Overall, 80 percent of post-splenectomy infections are caused by bacteria with capsular polysaccharides, particularly *S. pneumoniae* and *H. influenzae*.[124,131] Although *N. meningitidis* also has a polysaccharide capsule, lack of terminal components of complement constitute the greatest risk for development of infection and whether the incidence of sepsis is higher in persons with asplenia is unclear. However, because overwhelming meningococcal sepsis has been reported in patients with asplenia, it is reasonable to include these patients as an at-risk population for this pathogen.

To reduce the likelihood of serious infections after splenectomy, several measures are advisable. Splenectomy should be performed only when it is absolutely indicated. If possible, the best approach is to delay the surgical intervention until the child is 5 or 6 years of age. For children with congenital high-risk conditions, pneumococcal polysaccharide protein conjugate vaccines should be provided in the recommended schedules. Although multivalent pneumococcal polysaccharide vaccine provides incomplete protection for patients undergoing splenectomy, especially infants and young children, it should be administered to all patients who are older than 2 years, ideally 2 weeks before the splenectomy is performed.[127] Vaccination against *H. influenzae* type b and *N. meningitidis* types A, C, Y, and W-135 with the appropriate polysaccharide or polysaccharide-protein conjugate vaccine recommended for use in children should be provided.

For antibiotic prophylaxis, penicillin is the agent of choice. Penicillin V given twice daily (125 mg twice daily for children younger than 5 years; 250 mg twice daily for children older than 5 years) significantly decreases the frequency of invasive pneumococcal infection.

*References 11, 24, 48, 96, 119, 143.

Erythromycin and TMP-SMX are alternative options in patients with documented hypersensitivity to penicillin. The duration of prophylactic coverage remains controversial; current practice is to provide penicillin prophylaxis indefinitely in immunocompromised patients.[3,124]

Hemoglobinopathies

Functional asplenia is the primary reason for susceptibility to pneumococcal infection in children with sickle-cell anemia. Serum immunoglobulins are normal or increased in these children; however, they have a dysfunctional alternative complement pathway and decreased opsonic activity (which is mediated by both the alternative and the classic complement components) against *S. pneumoniae*. Leukocyte function also is defective in patients with sickle-cell anemia; intracellular production of hydrogen peroxide, respiratory stimulation, and hexose monophosphate shunt activity are inadequate during phagocytosis. In contrast, leukocytes from splenectomized patients without sickle-cell anemia exhibit normal phagocytic function accompanied by adequate metabolic stimulation. Immunologic dysfunction occurs less rapidly and less commonly in children with hemoglobin C sickle-cell anemia and hemoglobin C β-thalassemia.[88]

Patients with sickle-cell disease are at risk for development of overwhelming infection (septicemia and meningitis) by encapsulated bacteria, including *S. pneumoniae*, *H. influenzae* type b, and, rarely, *N. meningitidis*. *S. pneumoniae* is the most important and frequent cause of septicemia and meningitis in these patients.[137] The risk is particularly high in children younger than age 3 years.[60] A trend toward increased frequency of invasive disease in the first 2 to 5 years after splenectomy also has been noted. Unlike very young children, school-aged children appear to be less vulnerable to pneumococcal invasive infection, even though they remain functionally asplenic.[61,137,140]

The efficacy of penicillin prophylaxis in preventing pneumococcal infection in infants and young children with sickle-cell disease has been well documented in several reports.* The recommended dose of penicillin V is 125 mg twice daily in children younger than 5 years and 250 mg twice daily in children 3 years or older. Some physicians recommend use of amoxicillin 20 mg/kg/day or TMP-SMX 4 mg TMP plus 20 mg SMX per kilogram daily in children younger than age 5 years to include coverage against *Haemophilus* organisms, which are less likely to be a concern in children who are immunized adequately.

Because overwhelming infection can occur in infants as young as 3 months of age, detection of sickle-cell anemia should be accomplished in the neonatal period. Infants in whom sickle-cell anemia is diagnosed should start a prophylactic antibiotic regimen no later than 3 to 4 months of age.[61] The optimal duration of prophylaxis is not defined clearly, and the age at which prophylactic penicillin can be discontinued safely is determined arbitrarily.[3] A concern is that penicillin prophylaxis may decrease the development of natural immunity against pneumococcal infection in children receiving prophylaxis, thereby rendering them more susceptible to development of infection after prophylaxis is discontinued.[26] Another concern is the accelerated development of penicillin-resistant strains of *S. pneumoniae*.[54,137] A multicenter study by the Prophylactic Penicillin Study II group suggests that in children with sickle-cell anemia who have not had a previous severe pneumococcal infection or surgical splenectomy and are receiving comprehensive care, prophylaxis may be stopped safely at 5 years of age.[54] Continuous prophylaxis has limitations, and serious overwhelming infection can occur while patients are receiving prophylaxis. Patients or parents (or both) should be aware that any febrile illness is potentially serious, and immediate medical attention should be sought.[40,110]

Cerebrospinal Fluid Leakage

The value of antibiotic prophylaxis in patients with cerebrospinal fluid leakage has not been proven.[58,101] In the absence of meningeal inflammation, many antibiotics do not penetrate the blood-brain barrier and do not attain adequate levels in cerebrospinal fluid. Antibiotic prophylaxis often fails and frequently alters the normal flora of the respiratory tract, thereby resulting in colonization with resistant bacteria. Prophylaxis may be considered for a short duration while surgical repair is being planned.[101]

SURGICAL PROPHYLAXIS

The goal of prophylactic administration of antibiotics prior and/or during surgery is to reduce or eliminate postoperative morbidity, shorten hospitalization, and reduce the overall costs attributable to infection. Wounds can be classified as clean, clean-contaminated, contaminated, and dirty. Table 236-7 provides the conditions for these wound categories. Dirty wounds are those with purulence or abscess or preoperative perforation of gastrointestinal, oropharyngeal biliary or tracheobronchial tracts or penetrating trauma with environmental flora. The appropriate doses for adults or children (by weight) are provided in Table 236-8[21] and Table 236-9.[132]

An effective prophylactic regimen should be directed against the most likely infecting organisms but need not eradicate every potential pathogen. Therefore, for most procedures, the first-generation cephalosporin cefazolin, which is active against many streptococci and staphylococci, remains effective. When operations involve the bowel with exposure to aerobic and anaerobic bowl flora, then several agents including second-generation cephalosporins (cefoxitin, cefotetan) or ampicillin/sulbactam may suffice alone or combinations such as cefazolin with metronidazole may be substituted; Vancomycin can be used for prophylaxis when frequent infections with methicillin-resistant *S. aureus* are prominent, but it may not be more effective than cefazolin, and persistent use may lead to the emergence of vancomycin-resistant organisms. It is common practice to give antibiotics at the time of anesthesia induction, which should result in adequate tissue and serum levels at the time of incision and interoperative tissue manipulation. For most procedures lasting less than 4 hours, a single

*References 3, 53, 60, 61, 110, 140.

TABLE 236-7 **Surgical Procedures and Probable Pathogens**

Surgical Category	Most Likely Pathogens
Clean	
Neurosurgical	CNS, *Staphylococcus aureus*
Cardiovascular	CNS, *S. aureus*
Orthopedic	CNS, *S. aureus*
Clean-Contaminated	
Burn	Group A streptococci, *S. aureus,* GNB
Gastrointestinal	GNB, anaerobes, enterococci
Urogenital	GNB, enterococci
Respiratory	α-Hemolytic streptococci, anaerobes
Contaminated	
Ruptured viscera	GNB, anaerobes, enterococci
Traumatic wounds	*S. aureus,* group A streptococci, clostridia

CNS, coagulase-negative staphylococci; GNB, gram-negative bacilli.

dose is recommended. Published studies often use one or two additional doses after the completion of surgery, but most experts do not believe that these are necessary, and no data support the use of antibiotics beyond 48 hours.

General Surgical Procedures

Skin incision, organ manipulation, and surgical trauma increase the likelihood for development of local infection. Surgical procedures traditionally are classified as clean, clean-contaminated, and contaminated (see Table 236-7). A fourth category of dirty wounds are those known to be contaminated, where prior to surgery the skin or visceral space was compromised, introducing normal bowel or skin flora, or by contamination with a large number of environmental bacteria. Prophylactic antibiotics are effective in reducing postoperative infections after contaminated and clean-contaminated surgical procedures, whereas their efficacy is more controversial for clean surgical procedures. Clean surgical procedures generally carry a risk for development of postoperative wound infection that is less than 5 percent and, in many hospitals, less than 1 percent.

The critical period for development of infection is short, and optimal prophylaxis should be restricted to the perioperative period. Antibiotic prophylaxis of less than 24 hours' duration is effective both clinically and experimentally. Administration of antibiotics should be started at the time of induction of anesthesia or immediately before the surgical incision is made and discontinued within 24 hours.

Addressing all situations of surgical prophylaxis is beyond the scope of this chapter, and the reader is referred to several publications and reviews on the subject.* Nationwide standards and goals for surgical prophylaxis have been established.[22] The consensus of these statements is that effective surgical prophylaxis must include the first dose of antimicrobial agents within 60 minutes before the surgical procedure and that dosing should be discontinued within 24 hours after the end of surgery. These documents and others provide the routine basis and evidence base for all current guidelines on surgical prophylaxis, including the recommended regimens and dosing for cardiothoracic, vascular, and abdominal or colonic surgery as well as hip or knee arthroplasty, vaginal or abdominal hysterectomy, and neurosurgical procedures.[9]

Neurosurgical Procedures

The use of prophylactic antibiotics for clean neurosurgical procedures remains controversial.[59,66,101,113] However, because of the perceived benefits of prophylactic antibiotics in uncontrolled trials involving a large number of patients, of whom adults were the majority, and in view of the scarcity of definitive studies, current recommendations support the use of a short-course prophylactic regimen.[27,50,64,112,138] Prophylaxis for clean neurosurgical procedures is particularly valuable for high-risk groups (e.g., patients undergoing operative procedures in excess of 4 hours, operations in which craniotomies are performed, or patients with major underlying disease).[28,46,121]

Placement of cerebrospinal fluid shunts is one of the most common neurosurgical procedures in pediatric patients. An estimated 10,000 new shunt insertions and 6,000 revisions are performed annually in the United States. The frequency of shunt infection varies from 1.5 to 39 percent (average, 10% to 15%).[85,116] The major route of infection is colonization of the device or the operative wounds during placement.[64] Retrograde spread from the distal end of the catheter or hematogenous seeding accounts for some instances of infection.

Most infections are noted within 15 days to 2 months of shunt placement.[89,116] Commensal skin flora are the predominant pathogens. Coagulase-negative staphylococci are the most common pathogens and account for approximately 70 percent of shunt infections. *S. aureus* is less common. Gram-negative bacilli are the least common and often are the result of retrograde infection from the peritoneum.[85,116]

The role of prophylactic antibiotics for placement of cerebrospinal fluid shunts has been controversial.[65] A meta-analysis of 1359 patients in 12 randomized, controlled trials indicated that short-term perioperative antimicrobial prophylaxis at the time of placement of a cerebrospinal fluid shunt significantly decreases the risk for subsequent development of device-related infection.[89] Various antimicrobial regimens, including antistaphylococcal penicillins, cephalosporins, TMP-SMX, vancomycin, gentamicin, and combinations, were used in these trials. The choice of an appropriate prophylactic regimen in a particular setting should be based on the local epidemiology of suspected pathogens, local patterns of antimicrobial susceptibility, cost, and expected toxicity. The duration of perioperative prophylaxis should not exceed 48 hours.[81,89] A longer duration of prophylaxis increases cost and the risk for development of adverse reactions and promotes alteration of the normal flora and the emergence of resistant bacteria.

TABLE 236-8 **Suggested Initial Dose and Time to Redosing for Antimicrobials Commonly Used for Surgical Prophylaxis**

Antimicrobial	Half-Life Normal Renal Function (hr)	Half-Life End-Stage Renal Disease (hr)	Recommended Infusion Time (min)	Standard Intravenous Dose (g)	Weight-Based Dose Recommendation* (mg)	Recommended Redosing Interval† (hr)
Aztreonam	1.5-2	6	3-5‡	1-2	Maximum 2 g (adults)	3-5
Ciprofloxacin	3.5-5	5-9	60	400 mg	400 mg	4-10
Cefazolin	1.2-2.5	40-0	3-5‡ 15-60§	1-2	20-30 mg/kg 1 g < 80 kg; 2 g ≥ 80 kg 2 g ≥ 80 kg	2-5
Cefuroxime	1-2	15-2	3-5‡ 15-60§	1.5	50 mg/kg	3-4
Cefamandole	0.5-2.1	12.3-18‖	3-5‡ 15-60§	1		3-4
Cefoxitin	0.5-1.1	6.5-23	3-5‡ 15-60§	1-2	20-40 mg/kg	2-3
Cefotetan	2.8-4.6	13-25	3-5‡ 20-60§	1-2	20-40 mg/kg	3-6
Clindamycin	2-5.1	3.5-5.0¶	10-60 (Do not exceed 30 mg/min)	600-900 mg	<10 kg: at least 37.5 mg ≥10 kg: 3-6 mg/kg	3-6
Erythromycin base	0.8-3	5-6	NA	1 g orally 19, 18, 9 hr before surgery	9-13 mg/kg	NA
Gentamicin	2-3	50-70	30-60	1.5 mg/kg**	See footnote**	3-6
Neomycin	2-3 hours (3% absorbed under normal gastrointestinal conditions)	12-≥24	NA	1 g orally 19, 18, 9 hr before surgery	20 mg/kg	NA
Metronidazole	6-14	7-21 no change	30-60	0.5-1	15 mg/kg (adult) 7.5 mg/kg on subsequent doses	6-8
Vancomycin	4-6	44.1-406.4 (Cl_{cr} <10 mL/min)	1 g ≥ 60 min (use longer infusion time if dose < 1 g)	1.0	10-15 mg/kg (adult)	6-12

*Weight-based doses are primarily from published pediatric recommendations.
†For procedures of long duration, antimicrobials should be redosed at intervals of 1 to 2 times the half-life of the drug. The intervals in the table were calculated for patients with normal renal function.
‡Dose injected directly into vein or running intravenous fluids.
§Intermittent intravenous infusion.
‖In patients with a serum creatinine 5 to 9 mg/dL.
¶The half-life of clindamycin is the same or slightly increased in patients with end-stage renal disease compared with patients with normal renal function.
**If the patient's weight is 30% above their ideal body weight, dosing weight can be determined as follows: DW = IBW + 0.4 (total body weight-IBW).
DW, dosing weight; IBW, ideal body weight; NA, not applicable.

TABLE 236-9 Antimicrobial Prophylaxis for Surgery

Nature of Operation	Common Pathogens	Recommended Antimicrobials	Usual Adult Dosage[1]
Cardiac			
	Staphylococcus aureus, Staphylococcus epidermidis	cefazolin	1-2 g IV[2,3]
		OR cefuroxime	1.5 g IV[3]
		OR vancomycin[4]	1 g IV
Gastrointestinal			
Esophageal, gastroduodenal	Enteric gram-negative bacilli, gram-positive cocci	High-risk[5] only: cefazolin[6]	1-2 g IV[2]
Biliary tract	Enteric gram-negative bacilli, enterococci, clostridia	High-risk[7] only: cefazolin[6,8]	1-2 g IV[2]
Colorectal	Enteric gram-negative bacilli, anaerobes, enterococci	*Oral:* neomycin + erythromycin base[9] or metronidazole[9]	See footnote 9
		Parenteral: cefoxitin[6] or cefotetan[6]	1-2 g IV
		OR cefazolin[6] + metronidazole	1-2 g IV[2] + 0.5 g IV
		OR ampicillin/sulbactam[6,10]	3 g IV
Appendectomy, non-perforated[11]	Same as for colorectal	cefoxitin[6] or cefotetan[6]	1-2 g IV
		OR cefazolin[6] + metronidazole	1-2 g IV[2] + 0.5 g IV
Genitourinary			
Cystoscopy alone	Enteric gram-negative bacilli, enterococci	High-risk[12] only: ciprofloxacin[10]	500 mg PO or 400 mg IV
		OR trimethoprim-sulfamethoxazole	1 DS tablet
Cystoscopy with manipulation or upper tract instrumentation[13]	Enteric gram-negative bacilli, enterococci	ciprofloxacin[10]	500 mg PO or 400 mg IV
		OR trimethoprim-sulfamethoxazole	1 DS tablet
Open or laparoscopic surgery[14]	Enteric gram-negative bacilli, enterococci	cefazolin[6]	1-2 g IV[2]
Gynecologic and Obstetric			
Vaginal, abdominal or laparoscopic hysterectomy	Enteric gram-negative bacilli, anaerobes, Gp B strep, enterococci	cefazolin,[6] cefoxitin[6] or cefotetan[6]	1-2 g IV[2]
		OR ampicillin/sulbactam[6,10]	3 g IV
Cesarean section	same as for hysterectomy	cefazolin[6]	1-2 g IV[2]
Abortion, surgical	same as for hysterectomy	doxycycline	300 mg PO[15]
Head and Neck Surgery			
Incisions through oral or pharyngeal mucosa	Anaerobes, enteric gram-negative bacilli, *S. aureus*	clindamycin	600-900 mg IV
		OR cefazolin + metronidazole	1-2 g IV[2] + 0.5 g IV
		OR ampicillin/sulbactam[10]	3 g IV
Neurosurgery			
	S. aureus, S. epidermidis	cefazolin	1-2 g IV[2]
		OR vancomycin[4]	1 g IV
Ophthalmic			
	S. epidermidis, S. aureus, streptococci, enteric gram-negative bacilli, *Pseudomonas* spp.	gentamicin, tobramycin, ciprofloxacin, gatifloxacin levofloxacin, moxifloxacin, ofloxacin or neomycin-gramicidin-polymyxin B	multiple drops topically over 2 to 24 hours
		OR cefazolin	100 mg subconjunctivally
Orthopedic			
	S. aureus, S. epidermidis	cefazolin[16]	1-2 g IV[2]
		OR vancomycin[4,16]	1 g IV
Thoracic (Non-Cardiac)			
	S. aureus, S. epidermidis, streptococci, enteric gram-negative bacilli	cefazolin	1-2 g IV[2]
		OR ampicillin/sulbactam[10]	3 g IV
		OR vancomycin[4]	1 g IV

Continued on following page

TABLE 236-9 **Antimicrobial Prophylaxis for Surgery** (Continued)

Nature of Operation	Common Pathogens	Recommended Antimicrobials	Usual Adult Dosage[1]
Vascular			
Arterial surgery involving a prosthesis, the abdominal aorta, or a groin incision	*S. aureus, S. epidermidis,* enteric gram-negative bacilli	cefazolin OR vancomycin[4]	1-2 g IV[2] 1 g IV
Lower extremity amputation for ischemia	*S. aureus, S. epidermidis,* enteric gram-negative bacilli, clostridia	cefazolin OR vancomycin[4]	1-2 g IV[2] 1 g IV

1. Parenteral prophylactic antimicrobials can be given as a single IV dose begun within 60 minutes before the procedure. For prolonged procedures (>3 hours) or those with major blood loss, or in patients with extensive burns, additional intraoperative doses should be given at intervals 1-2 times the half-life of the drug (ampicillin/sulbactam q2 hours, cefazolin q4 hours, cefuroxime q4 hours, cefoxitin q2 hours, clindamycin q6 hours, vancomycin q12 hours) for the duration of the procedure in patients with normal renal function. If vancomycin or a fluoroquinolone is used, the infusion should be started within 60-120 minutes before the initial incision to have adequate tissue levels at the time of incision and to minimize the possibility of an infusion reaction close to the time of induction of anesthesia.
2. The recommended dose of cefazolin is 1 g for patients who weigh <80 kg and 2 g for those ≥80 kg. Morbidly obese patients may need higher doses.
3. Some experts recommend an additional dose when patients are removed from bypass during open-heart surgery.
4. Vancomycin can be used in hospitals in which methicillin-resistant *S.* aureus and *S.* epidermidis are a frequent cause of postoperative wound infection, in patients previously colonized with MRSA, or for those who are allergic to penicillins or cephalosporins. Rapid IV administration may cause hypotension, which could be especially dangerous during induction of anesthesia. Even when the drug is given over 60 minutes, hypotension may occur; treatment with diphenhydramine (*Benadryl*, and others) and further slowing of the infusion rate may be helpful. Some experts would give 15 mg/kg of vancomycin to patients weighing more than 75 kg, up to a maximum of 1.5 g, with a slower infusion rate (90 minutes for 1.5 g). For procedures in which enteric gram-negative bacilli are common pathogens, many experts would add another drug such as an aminoglycoside (gentamicin, tobramycin or amikacin), aztreonam or a fluoroquinolone.
5. Morbid obesity, GI obstruction, decreased gastric acidity or GI motility, gastric bleeding, malignancy or perforation, or immunosuppression.
6. For patients allergic to penicillins and cephalosporins, clindamycin or vancomycin with either gentamicin, ciprofloxacin, levofloxacin or aztreonam is a reasonable alternative. Fluoroquinolones should not be used for prophylaxis in cesarean section.
7. Age >70 years, acute cholecystitis, non-functioning gall bladder, obstructive jaundice or common bile duct stones.
8. Cefotetan, cefoxitin and ampicillin-sulbactam are reasonable alternatives.
9. In addition to mechanical bowel preparation, 1 g of neomycin plus 1 g of erythromycin at 1 PM, 2 PM and 11 PM or 2 g of neomycin plus 2 g of metronidazole at 7 PM and 11 PM the day before an 8 AM operation.
10. Due to increasing resistance of *E. coli* to fluoroquinolones and ampicillin/sulbactam, local sensitivity profiles should be reviewed prior to use.
11. For a ruptured viscus, therapy is often continued for about five days.
12. Urine culture positive or unavailable, preoperative catheter, transrectal prostatic biopsy, or placement of prosthetic material.
13. Shock wave lithotripsy, ureteroscopy.
14. Including percutaneous renal surgery, procedures with entry into the urinary tract, and those involving implantation of a prosthesis. If manipulation of bowel is involved, prophylaxis is given according to colorectal guidelines.
15. Divided into 100 mg before the procedure and 200 mg after.
16. If a tourniquet is to be used in the procedure, the entire dose of antibiotic must be infused prior to its inflation.

Cardiovascular Surgery

Infectious complications of cardiovascular surgery can be very serious and life-threatening, and antimicrobial prophylaxis is used commonly in most medical centers.[80,86] Most available data are based on reports from adult patients,[39,67] with little specific information available on prophylactic antibiotic use in pediatric patients. The goal of prophylactic therapy is prevention of wound infection, mediastinitis, and endocarditis. A survey of 43 North American academic centers with pediatric cardiovascular surgery programs indicated that all centers use prophylactic antibiotics for all operative procedures.[91] Monotherapy prophylaxis was used by 91 percent of respondents and consisted almost exclusively of a first- or second-generation cephalosporin. In 95 percent of centers, prophylaxis was started just before surgery or intraoperatively. Prophylaxis was continued for 48 hours or less in most (68%) instances. Prophylactic antibiotics often were continued while thoracostomy tubes, mediastinal tubes, or transthoracic vascular catheters were in place but usually not for endotracheal tubes, arterial or percutaneous central venous catheters, or temporary pacing wires.

CHAPTER 237

Outpatient Intravenous Antimicrobial Therapy for Serious Infections

John S. Bradley

Outpatient parenteral antimicrobial therapy (OPAT) is the means by which children can receive the benefits of parenteral (intravenous or intramuscular) therapy in an outpatient setting, usually the home, avoiding hospitalization with the associated exposure to nosocomial pathogens, inpatient costs, and psychological stress for child and family. The widespread acceptance of OPAT by physicians, families, and insurers has led to a tremendous increase in the outpatient treatment of serious infectious diseases.* The standard of care provided to children through OPAT should equal or surpass that provided to hospitalized children. National guidelines for OPAT in adults and children have been published by the Infectious Diseases Society of America and define both benefits and risks.[53] This chapter explains the basic concepts behind OPAT for children. The OPAT team, which includes the physician, OPAT coordinator, nurse, pharmacist, parent or caregiver, and third-party payer, needs to work closely to ensure a successful outcome for the child.

TABLE 237-1 **Medical and Social Criteria for Outpatient Parenteral Antimicrobial Therapy**

Medical Criteria for OPAT
Medical diagnosis of infection with a suspected or documented pathogen
Clinical response to anti-infective therapy (if therapy is started in the hospital)
No assessed need for urgent medical, surgical, or laboratory interventions to achieve a clinical response to anti-infective therapy
No significant risk for complications of the infection
No requirement for continuous skilled nursing care
Social Criteria for OPAT
Parents interested and motivated
Parents capable of assessing the child for complications of infection and therapy
24-hour telephone access to the OPAT team
Transportation for timely return to the clinic or hospital, if needed
Home environment acceptable and resources available
Parents documented to be capable of administering parenteral anti-infective agents, if required, before OPAT begins

OPAT, Outpatient parenteral antimicrobial therapy.

aspect in the assessment of a newborn, infant, or child for OPAT is a determination that ongoing parenteral therapy is required to treat the infection appropriately and that continuous skilled nursing observation and care are not required for management. Development of complications of the infection in the child should be considered highly unlikely by the time OPAT is undertaken; unskilled clinical observations by the parents or caregivers should be considered adequate for care. No additional significant risk should be placed on the child's recovery by enrollment in an OPAT program. Whenever possible, oral antibiotic therapy should be used instead of parenteral therapy. Recent options for oral therapy include agents such as the fluoroquinolones ciprofloxacin and levofloxacin, and an oxazolidinone, linezolid, that have excellent absorption and tissue exposure characteristics, but may be more costly or have some potential toxicities that may not be present with older generic antibiotics.

A child usually is prescribed an OPAT regimen from either a hospital setting after inpatient intravenous therapy or an outpatient setting such as a clinic or emergency department. For a child being discharged from the hospital, an unequivocal response to parenteral anti-infective therapy should be demonstrated. Most often, appropriate cultures will have directed the use of anti-infective therapy active against the isolated pathogens. For children with no positive cultures, the signs and symptoms of the infection should be resolving with empirical therapy, as demonstrated by decreasing fever and improving function. The child's infection should be judged by the clinician to be unlikely to progress or to result in complications. No further surgical or medical interventions should be anticipated during the remainder of the parenteral antimicrobial therapy course.

The child's clinical course during receipt of OPAT needs to be monitored to be certain that the anticipated response continues to occur. An outpatient visit usually is scheduled for a few days after discharge.

Before a child is enrolled in OPAT, an assessment of the parents or caregivers also is required (see Table 237-1). Because the parents are responsible for the nursing care of their child in the home, they must be willing and capable participants. Although most parents are very interested and highly motivated to return home with their child, not all are willing to perform or are capable of performing the required nursing functions. Most parents are capable of providing limited medical assessment of their children, but, unfortunately, some are not. In addition, the home environment should have the resources required for the proposed medical care. For example, intravenous therapy administered to a child through a tunneled, central catheter requires local sterile conditions for anti-infective drug infusions and dressing changes, which will require the availability of a clean room with running water, and a refrigerator if storage of antimicrobials and diluents is necessary. Less stringent criteria clearly would apply for a child visiting the outpatient clinic daily to receive intramuscular antibiotic injections. Communication between the parents and medical personnel is essential. For parents or caregivers, telephone access to nurses and clinicians is critical. In addition, the parents should be able to bring their child back to the hospital or clinic for reevaluation if complications arise either from the infection or from therapy. Hence, access to adequate transportation within a medically appropriate time frame is required. Families with no available transportation, families who live in rural areas located several hours' travel from a medical facility, and OPAT during the winter season in which weather conditions may severely limit travel, all should be considered before OPAT is started. In addition to observing their child and communicating information to medical providers, many parents may be asked to infuse anti-infective agents intravenously into their children. Doing so requires an additional level of skill in the parent or caregiver and assessment of parental competence for this function by the OPAT nursing and medical personnel.

THE OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY PROGRAM

The roles of physicians, OPAT coordinators, nurses, pharmacists, and parents or patients have been defined previously (Table 237-2).[53] Once the clinician considers that the child's condition is sufficiently stable to pursue intravenous outpatient therapy from a hospital ward, a clinic, or an emergency department setting, the coordinator of the outpatient treatment program is notified. This person is capable of assessing the feasibility of implementing OPAT for that particular child and family and assessing reimbursement by third party payers and obtaining authorizations, if needed. The OPAT coordinator interviews parents and medical staff to determine the parents' willingness and their abilities and to assess

OPAT, Outpatient parenteral antimicrobial therapy.

the home environment. After the clinician prescribes the anti-infective agents, required nursing visits, ongoing laboratory and imaging tests, and follow-up clinic visits, the OPAT coordinator puts together the resources required for successful therapy. With knowledge of the parents' abilities and resources, the medication and equipment requirements, and the home nursing visits required, the coordinator makes the final determination about the feasibility of the program. As noted, the coordinator may need to obtain authorization from third-party payers; many insurance companies require a much greater financial contribution by families for the cost of care once a child is discharged, in contrast to their obligation for ongoing inpatient hospital charges. An example of an OPAT physician's order form that includes catheter management and medication orders, laboratory and imaging test orders, and clinic visits is shown in Figure 237-1. The coordinator of the OPAT program, whether it is clinic or hospital based, should ensure that open lines of communication exist among the clinician, the home visiting nurse, the pharmacist, and the parents. A defined, written plan for medical and nursing care should be established. All members of the OPAT team should be aware of their responsibilities.

OPAT may be provided by periodic visits to the clinic, emergency department, or day infusion center[20] or be provided in the home by visiting nurses and parents. For children receiving therapy at home, the frequency of the required home pediatric nursing visits needs to be individualized for each child and depends on many factors—the clinical course while the child is receiving therapy, the seriousness of the infection, the ability of the parents to effectively examine the child, and the risk for development of complications that can be related to either the infection or therapy. For most children, the frequency of home nursing visits will be greatest at the beginning of OPAT, often once daily. After treatment at home has been delivered as anticipated and recovery from infection is proceeding as expected, visits may be decreased to two or three times each week, particularly if the parents have demonstrated competency in providing nursing care, including managing an intravenous catheter, changing wound dressings, and providing clinical assessment. The home visiting nurse also may have the opportunity to establish ongoing assessment of the parents' ability to administer anti-infective agents in the home.

Physical assessment of neonates receiving OPAT may be particularly difficult for parents, and daily visits throughout the entire course of therapy by skilled pediatric home visiting nurses may be required. Daily visits also are important for children with less stable infections, such as central nervous system infections, because subtleties in the neurologic examination findings may not be appreciated by parents or caregivers and may provide clues to impending problems. Nursing aspects of pediatric OPAT have been outlined by successful programs.[26,33,49]

FIGURE 237-1 ■ An example of a physician's order sheet for outpatient intravenous antimicrobial therapy (OPAT) for serious infections at Rady Children's Hospital San Diego, San Diego, California.

Pediatric competency in nursing is not standardized. Each state government in the United States licenses nurses on the basis of criteria specific for that state. However, just as for inpatient pediatric care, pediatric experience is an important qualification for the home visiting nurse caring for children. Unfortunately, home nursing agencies providing care to children are not required to have expertise in pediatric nursing. Therefore, considerable discrepancy exists in pediatric competency among nursing agencies. Given the importance of pediatric expertise in evaluation and management of infected children in the home, the home nursing agency contracted to provide care is expected to have personnel with training and experience equivalent to that of nurses providing care in a pediatric inpatient setting. The home nursing agency should be able to document proficiency in delivering care to newborns, infants, and children to the clinician and the OPAT coordinator.

In many states, only licensed nurses (registered nurses and licensed vocational nurses) may infuse anti-infective agents. However, most states have no rules prohibiting parents from administering drugs. Accordingly, parents may be expected to infuse medications to their children if licensed nurses are not deemed by the home care agency and the physician to be necessary to provide this function. The physician should be aware of the qualifications of the personnel responsible for the intravenous infusion of anti-infective agents.

The home visiting nurse should communicate with the physician about the medical status (e.g., the medical stability) of the child and plans for follow-up, before OPAT is started. Analogous to inpatient care, the nurses and physicians are expected to be on-call 24 hours each day.

Similarly, the pharmacist providing anti-infective therapy for OPAT should be familiar with the dosages and side effects of therapy provided to all pediatric age groups, from newborns to adolescents. Dosing errors in infants and children are not uncommon occurrences in health care facilities, given the broad range of doses administered.[29]

The parents should have written instructions for the tasks they are required to perform in the home, including information on sterile technique, administration of antimicrobials through sterile tubing and valves, flushing of catheters, and dressing changes. Their proficiency in management of the catheter and infusion of anti-infective agents should be demonstrated before the child is discharged from the hospital, emergency department, or clinic, because some parents or caregivers may not be capable of performing these tasks adequately. Telephone numbers should be provided for the 24-hour on-call nursing and physician personnel. A list of complications of the medications and information on how the parent should perform a clinical assessment of the child's infection should be provided, along with a set of parameters requiring immediate notification of medical personnel. Plans for disposal of needles, dressings, and other medical waste also should be made before the child is sent home.

Visits to clinicians (i.e., primary care providers, surgeons, subspecialists) are scheduled as necessary according to the clinical status of the child and the degree of expertise required by the examiner. If the child is stable in an outpatient setting, once-weekly visits to a physician usually are sufficient unless the home visiting nurse or parent observes problems requiring more immediate attention. For any high-risk, relatively unstable child, daily physician visits may be important, particularly if skilled pediatric home nursing is not available.

Although abuse of intravenous access seldom occurs, for an adolescent who may have a history of alcohol or drug dependence, the clinician should be particularly cautious in approving OPAT. For younger children with indwelling catheters, Münchausen syndrome by proxy may be a concern for infants and children who do not recover clinically as anticipated or have repeated, unanticipated complications.

INFECTIONS SUITABLE FOR OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY

Virtually any infection can be treated by OPAT at some point in the course of therapy by following the criteria listed in Table 237-1. For each child, a thorough assessment of the risks for development of complications of the infection must be made before outpatient therapy is considered. A partial list of infections treated with OPAT is given in Table 237-3; most of the studies are not prospective, randomized investigations comparing children receiving therapy in the hospital with those receiving therapy outside the hospital. The variety of infections that have been treated with OPAT at some point include bloodstream infections, such as bacteremia, catheter sepsis, and endocarditis; central nervous system infections, including meningitis, epidural abscess, subdural empyema, and brain abscess; osteomyelitis and septic arthritis; urinary tract infections; upper respiratory tract infections, including severe acute otitis media, chronic suppurative otitis, and mastoiditis; lower respiratory tract infections, including lung abscess and empyema; fever with or without neutropenia in low-risk immunocompromised children; neonatal bacterial sepsis; intra-abdominal infections; and postoperative wound infections.

DELIVERY OF ANTIMICROBIAL THERAPY

Selection of an Antimicrobial Agent

Selection of antimicrobial therapy for OPAT is similar to selection of therapy for any child in that the primary goal is to achieve clinical and microbiologic cure with the most efficacious, least toxic, and most cost-effective agents. Selection of an agent that is more convenient to administer but that may not be as effective is not appropriate. However, of the agents that demonstrate equivalent activity against the child's pathogen, the preferred agent is the one that is given least frequently, is nontoxic, and requires the least frequent monitoring for adverse events. Preferred agents for the most common community-acquired pathogens are given in Table 237-4. Almost any pathogen, community acquired or nosocomial, bacterial,

OPAT, Outpatient parenteral antimicrobial therapy.

fungal, or viral, can be treated in the home if the medical and social criteria for OPAT can be met.

In general, β-lactam agents (i.e., penicillins, cephalosporins, and carbapenems) require less frequent monitoring than do aminoglycosides (i.e., gentamicin, tobramycin, and amikacin), glycopeptides (i.e., vancomycin and teicoplanin), or oxazolidinones (e.g., linezolid). Agents that can be given intravenously during the course of a short period (5 to 15 minutes), such as β-lactam agents, are preferred to those that require up to an hour with each infusion (e.g., aminoglycosides and glycopeptides). Agents that can be given intramuscularly if intravenous access is temporarily lost are preferred to those that may be given only intravenously. Not only are these parameters designed to provide the optimal clinical outcome with minimal toxicity, they also are designed to facilitate therapy in the home. Dosing more frequently than every 8 hours poses a formidable challenge to many families, particularly those without extensive family support. Administration of two or three antibiotics that each require dosing three or four times each day is virtually impossible for most families to accomplish. These parameters are designed to maximize the potential for parents to be able to provide care at home with minimal risk. Although more frequent nursing visits may provide relief to parents, the charges for home nursing visits to administer therapy and to provide nursing care (e.g., wound dressing changes) are substantial; the charge for three nursing visits each day approaches the cost of a day in the hospital for a stable child, and most agencies do not have sufficient staff to provide more than one visit each day to a family.

Cytomegalovirus	Ganciclovir	12-24	Neutropenia

*If organisms are documented to be susceptible.
†Preferred agents based on dosing frequency and side effects.
‡Requires monitoring of renal function and serum concentrations.
§Not indicated for therapy unless no other therapy options exist.

Depending on the agent used, monitoring for antimicrobial toxicity in the outpatient setting should occur with the same frequency as that in the inpatient setting. Monitoring of renal function and serum antibiotic concentrations is important for children being treated with aminoglycosides or vancomycin. For children receiving long-term β-lactam therapy, periodic monitoring of the peripheral white blood cell count and renal and hepatic function every 2 to 4 weeks may detect the uncommon but well-described antibiotic-mediated toxicities of this class of antibiotics before any clinical manifestations occur.

Delivery of Antimicrobial Agents

OPAT can be delivered by intramuscular or intravenous injection. In general, the need for more than two or three injections necessitates intravenous therapy. However, once-daily intramuscular therapy lasting 1 week or longer has not been associated with short-term complications in anecdotal reports.[5,6] Short polyethylene catheters normally used for inpatient intravenous therapy may be used for short-term therapy lasting less than 5 to 7 days.[20] On occasion, intravenous access will be lost and the child will need to be reevaluated for ongoing parenteral therapy; if clinical improvement exceeds expectations, an early switch to oral convalescent therapy may be possible. If not, intravenous access may need to be reestablished. It may be performed in the home but more often will require the child and parent to return to the clinic or hospital. An intramuscular injection or injections may be given temporarily in the home, clinic, or emergency department until the intravenous catheter can be replaced.

For therapy lasting longer than 5 to 7 days, central catheters are preferred. Peripherally inserted central catheters (PICC lines) are widely available, practical, and cost-effective and have become the intravenous access of choice for extended therapy.[24,34,52,54] These catheters may be inserted through many different peripheral sites (usually the antecubital vein) by physicians or nurses with training in the placement of central catheters. Sedation usually is required for younger infants and children. Alternatively, more traditional subcutaneously tunneled central catheters with one or more ports (e.g., Hickman or Groshong) may be placed by a surgeon in the operating room with the child under general anesthesia. These tunneled catheters, which also may be used for blood sampling, are preferred for children requiring several weeks of therapy with agents that require periodic blood tests for assessment of organ function and serum antibiotic concentrations. Each type of central catheter requires sterile techniques for accessing the catheter and close monitoring of the catheter exit site during administration of therapy. The home visiting nurse agency should have written protocols for the care and use of central catheters that are consistent with standards set by The Joint Commission (TJC) (formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]), which will provide a program for Home Care Accreditation in 2013.[50]

Anti-infective agents may be infused directly into the catheter by the caregiver by way of an antibiotic-containing syringe simply attached to the catheter hub ("IV push"), followed by flushing of the catheter with saline or a heparin-containing solution. This method is often used for β-lactam agents. Alternatively, particularly for agents that cannot be infused quickly, an intravenous drip system must be used, or the agent must be infused by a pump. Pumps come in three basic designs: those with no electronic or moving parts; syringe pumps, in which the syringe containing the anti-infective agent is placed in a motorized pump designed to administer the dose during the course of a certain period; and electronic programmable pumps, which may have a variety of pump mechanisms and are programmed to control infusions of one or more agents administered during the course of different periods.

The least expensive pumps are those with no moving parts. One type of pump requires injection of the antibiotic solution, under some pressure, into a thick elastomeric "balloon." The pressure used to inject the antibiotic into the balloon then pushes the antibiotic through an infusion rate–limiting valve into the intravenous line and subsequently into the child. Other types of pumps are designed to place the antibiotic solution into a bag that then is placed into a device in which spring-loaded plates press on the solution contained in the bag, again pushing the antibiotic into the child through an infusion rate–limiting valve. These pumps generally use disposable infusion containers and are adequate for treatment with a single antibiotic administered up to a few times each day.

New tools for OPAT are becoming available each year. Resource guides to the equipment used for OPAT are available.[40] Unfortunately, for children, most of the equipment and resources available are designed for adults.

OUTCOME ANALYSIS

The anticipated outcome in the treatment of an infection is clinical and microbiologic cure with no complications of therapy. Although the psychosocial benefits of OPAT for children from a secure home environment were the original impetus for the establishment of pediatric programs, the economic benefits of outpatient therapy have been easier to document for both adults and children, although current published data in children are sparse.* The cost of treatment is substantially less for outpatient therapy when neither hospital facilities nor 24-hour skilled nursing care is necessary. With shorter periods of hospitalization, the risk for acquiring a nosocomial viral or bacterial infection should diminish and further decrease the overall cost of care.

However, complications may occur in children receiving OPAT, just as they occur in inpatients.[12,19,20,27,32,43] The infection being treated may not be under control or may relapse while the child is being monitored by parents or home nursing personnel. Errors in antibiotic dosing and administration may occur,[29] particularly if parents are given the responsibility of preparing and administering antibiotics in the home. Complications of anti-infective therapy, including adverse drug reactions, may increase when the number of anti-infective agents and doses administered to a child increases. In one pediatric study of children receiving long-term therapy for osteomyelitis, 51 percent of courses in 54 children were associated with adverse drug events.[12] Catheter- and pump-related complications often arise during therapy, with 26 percent of 98 children in one study having catheter complications, most commonly occlusion or clotting and dislodgement, also related to longer duration of therapy.[24,27,43] Parents may not be compliant with clinic visits and may not be in the home when the home nursing agency has

*References 4, 7, 21, 22, 25, 28, 36, 56, 60-62.

scheduled a visit. Family members or neighbors other than those trained to care for the child may provide care without the knowledge of the home nursing agency or physician. The clinician may need to rehospitalize the child if doing so is required to complete parenteral therapy safely.

TJC publishes standards and reviews home care outcomes by evaluating specified parameters, including unscheduled inpatient admissions, early discontinuation of parenteral therapy, interruptions in parenteral therapy, catheter-related infections, and adverse drug reactions.[51]

Until recently, data on outcomes from various home nursing agencies were not made available to contracting physicians, hospitals, or payers. Outcome data now are required to be collected by home health organizations, which eventually will help standardize the assessment of OPAT programs. The physician or OPAT coordinator should request outcomes data from any home nursing agency proposing to care for a child by OPAT.

SUMMARY

Successful use of OPAT requires integrated delivery of care for children who are assessed to be at low risk for development of complications from their infections and therapy and do not require skilled nursing care. Parents fulfill the role of a pediatric nurse in the hospital and should be capable of providing a focused, limited assessment of their child and communicating any concerning changes in the child's medical condition or concerns regarding adverse drug reactions or catheter or pump malfunction to the appropriate medical personnel. The anti-infective agents, infusion equipment, and medical follow-up all should be designed for the outpatient setting compatible with the training and resources available to parents or caregivers in the home. Outcomes of pediatric OPAT should be equivalent to or better than those achieved in an inpatient setting.

CHAPTER 238

ANTIVIRAL AGENTS

Gail J. Harrison

HISTORY AND BACKGROUND

The age of modern antiviral therapy began in the early 1950s, when methisazone, a derivative of the thiosemicarbazones (early antituberculosis compounds), was found also to have activity against vaccinia and variola viruses.* In 1959, the first antiherpes compound, idoxuridine, was synthesized; in 1962, it was approved for the topical treatment of herpetic keratitis.[294,429] Shortly thereafter, in 1964, trifluridine also was used to treat herpetic

keratitis.[295,296] Also in 1964, the first description of vidarabine as an antiviral agent active against herpes simplex virus (HSV) was published, and amantadine was shown to have activity against influenza virus.[124,467] Two years later, amantadine was approved first for the prophylaxis and subsequently for the treatment of influenza A virus infection.[469] Shortly thereafter, in 1972, vidarabine was approved for the treatment of herpes encephalitis.[556] The year 1972 also marked the first description of ribavirin as a broad-spectrum antiviral agent, with activity against both DNA and RNA viruses, and in 1985, the aerosolized form of the drug was approved for the treatment of respiratory syncytial virus (RSV) bronchiolitis.[127,518] In 1977, acyclovir was reported to be a potent and selective inhibitor of the replication of both HSV and varicella-zoster virus (VZV) and boasted the added advantage of a favorable safety profile.[126,151,503] Subsequently, several structural analogues of acyclovir led to the development of antiviral agents with expanded antiviral spectra, such as ganciclovir, and agents with more favorable bioavailability, such as with the prodrugs valacyclovir and valganciclovir.[116,356] In the 1990s, the introduction of cidofovir, a broad-spectrum, long-lasting antiviral agent, and the neuraminidase inhibitors zanamivir and oseltamivir, which treat both influenza A and influenza B viruses, added new dimensions to antiviral therapy.[77,113,327,493] The research now being conducted no doubt will expand our antiviral armamentarium to combat viruses that may be used as biologic weapons as well as to prevent the emergence of resistant viruses and spawn creative strategies such as multidrug therapy and targeted delivery systems.[190,226]

Even though diseases caused by viruses (Table 238-1) now may be treated with a variety of antiviral agents, the close relationship between the viral replicative cycle and its host cell metabolism unfortunately has caused the development of safe and effective antiviral agents to lag behind the development of other antimicrobials, such as antibiotics and antifungals. Clinically successful antiviral agents target and inhibit virus-specific functions while keeping cellular toxicity to a minimum. In addition, as a further testament to the codependency between viruses and host cells, some antiviral agents actually require cellular metabolism for antiviral activity, such as the terminal phosphorylation of acyclovir monophosphate to the active triphosphate form.

Antiviral agents can be categorized as virucidals, antiviral chemotherapeutic agents or drugs, and immunomodulators. Virucidal agents inactivate the virus on contact and include detergents, solvents, and ultraviolet light. These agents are not useful for treatment of human viral disease because healthy tissue also is destroyed. They may, however, be used to inactivate viruses on the surface of the skin or inanimate objects. Antiviral treatments that

physically destroy both virus and the tissues infected or transformed by them include cryotherapy, laser therapy, and podophyllin and are used primarily to treat recalcitrant or life-threatening warts on mucocutaneous or laryngotracheal tissue. The host immune response also is important and in many cases essential for recovery from viral disease or even maintenance of a latent or inactivated state of the virus. Therefore, successful antiviral treatment may necessitate relief from immunosuppression when it is feasible, such as for patients with Epstein-Barr virus (EBV)–induced lymphoproliferative disease who are undergoing cancer chemotherapy or organ transplantation. It also may include the use of biologic response modifiers, or immunomodulators, that manipulate the immune system to enhance its ability to contain viral infection. Examples of immunomodulators include immune globulin and monoclonal antibody preparations, cytokines such as interferons, and even novel approaches such as virus-specific cytotoxic T-cell lines designed to reconstitute host immunity.[21,35] In addition, supportive treatments including fluid resuscitation, blood product transfusions, mechanical ventilation, and extracorporeal membrane oxygenation are important for serious viral disease.[23,109] Finally, updated knowledge about specific antiviral therapy licensed for hepatitis viruses is reviewed in Chapters 47, 156, and 176, and antiretroviral therapy is reviewed in Chapter 191.

Antiviral chemotherapeutic agents usually inhibit virus-specific events (Fig. 238-1), such as adsorption or attachment to the host cell (pleconaril), penetration and uncoating of the viral genome (amantadine), viral gene expression and nucleic acid synthesis (acyclovir, ganciclovir), and even viral assembly of intact, infectious viral particles (interferons). Therefore, antiviral agents exhibit their "antiviral effect" primarily while viral replication is active at the host cell level. If the antiviral compound is withdrawn or discontinued, viral replication resumes. Furthermore, the currently available antiviral agents do not appear to eliminate viruses that are latent or in other dormant or nonreplicative states. The goal of antiviral therapy, for the most part, is to inhibit active viral replication to such a degree that the host immune response is able to contain or in some instances even to eliminate the infection.

Antiviral agents usually have a narrow range of activity that can be predicted by their molecular mechanism of

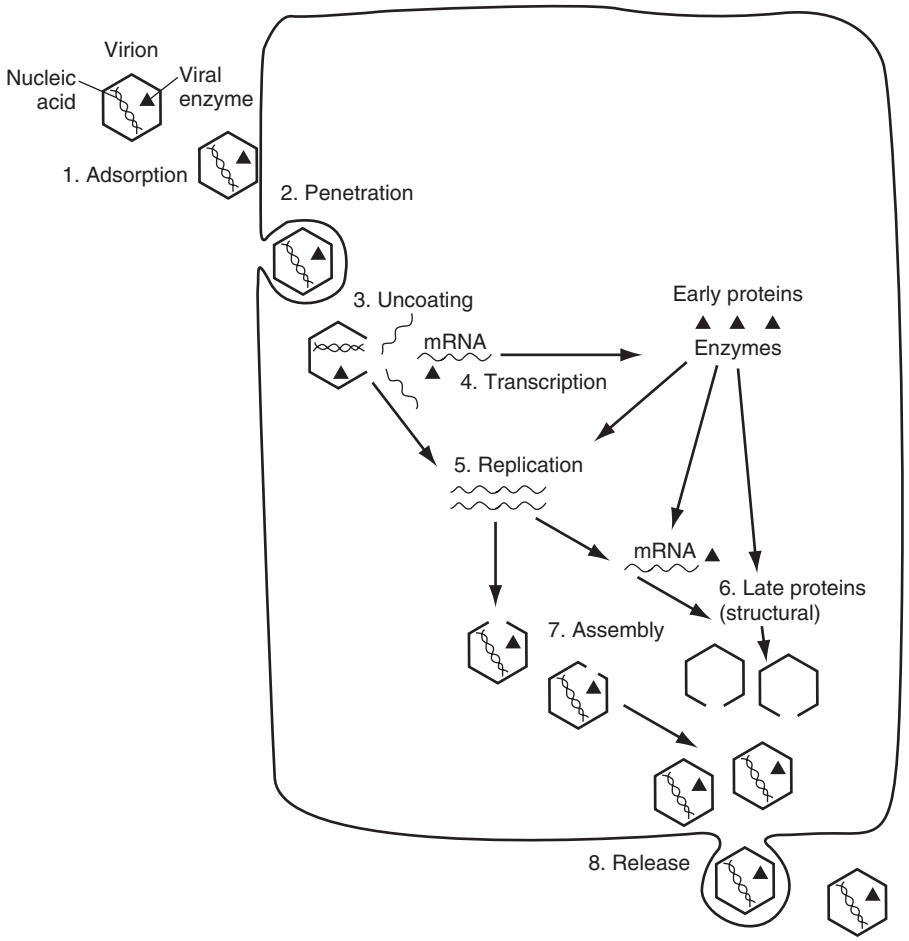

FIGURE 238-1 ■ Basic steps in intracellular (DNA) replication. *1,* Adsorption of virion to the cell membrane. *2,* Penetration. *3,* Uncoating, removal of the protein coat. *4,* Early gene expression, transcription of viral proteins. *5,* Replication, synthesis of DNA strands. *6,* Late gene expression, transcription of messenger RNA, and translation of late protein synthesis. *7,* Maturation and assembly of virions. *8,* Release.

action. For example, rimantadine and amantadine have high activity against the RNA-containing influenza A virus, limited activity against influenza B virus, and virtually no activity against the DNA herpesviruses,[113,124] whereas acyclovir, a deoxyguanosine analogue that requires monophosphorylation by the viral enzyme thymidine kinase (TK) for activation, has significant activity against DNA viruses (HSV), which carry TK, but no activity against RNA viruses such as influenza virus. Viruses infecting a host also may become resistant to a specific agent to which they originally were susceptible, usually by induced or selected mutations. Resistance is therefore most likely to occur in viruses that infect the host with a high viral load and that have a high intrinsic viral mutation rate as well as in viruses that infect hosts who are exposed to selective drug pressure during chronic, low-dose, or repeated treatment with an antiviral agent.[249] Both resistant and sensitive viruses are capable of causing serious disease, especially in an immunocompromised host. Currently, most antiviral agents are administered as single therapeutic agents. However, double and triple combination antiviral drug therapy, now a routine therapy in modern antiretroviral regimens, is also important in selected circumstances for treatment of other viral diseases in immunocompromised hosts or where presence or emergence of drug-resistant viruses is likely.[24,221,226,400,401] Combination strategy increases antiviral effectiveness, prevents the emergence of drug resistance, and allows the administration of lower, less toxic dosages.*

ANTIVIRAL AGENTS ACTIVE AGAINST RNA VIRUSES (Table 238-2)

Amantadine and Rimantadine

Spectrum of Activity

Amantadine (1-adamantanamine hydrochloride) and rimantadine (α-methyl-1-adamantane methylamine hydrochloride) are tricyclic amines with specific activity against influenza A viruses (Fig. 238-2). Mean inhibitory concentrations of 0.1 to 0.4 μg/mL for amantadine have been reported, and rimantadine is 4 to 10 times more active than amantadine against susceptible subtypes of influenza A virus.[72,224,422] Amantadine also has in vitro activity against rubella virus, but efficacy was not confirmed in animal models.[409,410,468,508] Much higher concentrations (10 to 50 μg/mL) appear to inhibit influenza B virus and parainfluenza viruses, but these high concentrations cannot be achieved safely in humans.[468] Research and development continue with designs of more adamantane-like inhibitors of the M2 proton channel against influenza A virus.[144,422] The adamantanes also have significant activity against hepatitis C virus (HCV) and rhabdoviruses (vesicular stomatitis virus and rabies virus).[480,490,560]

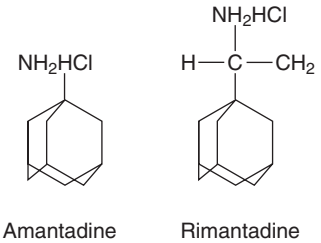

FIGURE 238-2 ■ Structure of amantadine and rimantadine.

Mechanism of Action and Resistance

The mechanism of action of both amantadine and rimantadine against influenza A virus appears to be primarily inhibition of the ion channel function of the M2 protein in the membrane of the virus, possibly affecting two stages of viral replication, uncoating and, to a lesser extent, assembly.[22,113,220,422] Amantadine and rimantadine resistance occurs when mutations cause an amino acid change in one of four critical sites (amino acids 26, 27, 30, and 31) in the transmembrane channel or domain of the M2 viral protein.[313] Such mutations occur frequently and rapidly during therapy because approximately 30 percent of adults and children who receive amantadine or rimantadine therapy for at least 5 days shed resistant influenza virus.[222,225] These resistant strains are genetically stable, may be transmitted to close contacts, and can produce disease.[44,222,579] Immunocompromised patients may shed drug-resistant influenza viruses for prolonged periods, and resistant strains can persist even after drug administration has been discontinued.[313] However, debate has begun among experts concerning whether patients in whom a resistant strain is identified should be isolated until viral shedding has ceased.[211] Adamantane-resistant strains of influenza A subtype H3N2 and subtype H1N12009 have produced community outbreaks and epidemics.[44,222,235,579] Some strains of highly pathogenic A(H5N1) avian influenza are susceptible to adamantanes, but most strains of A(H5N1) should be considered

TABLE 238-2 **Clinical Indications and Usual Treatment Dosages for Antiviral Agents Active Against RNA Viruses**

Agent	Indication	Dosage
Amantadine	Influenza A	2.2-4.4 mg/kg/dose PO bid (max, 100-200 mg daily)
Rimantadine	Influenza A	2.5 mg/kg/dose PO bid (max, 150 mg daily)
Oseltamivir	Influenza A and B	2 mg/kg/dose PO bid (max, 150 mg daily)
Zanamivir	Influenza A and B	5 mg/dose inhaled bid
Ribavirin	Respiratory syncytial virus	6 g/300 mL inhaled daily in an 18-hr period
		or
		2-6 g/100 mL inhaled in a 2-hr period tid
	Hepatitis C	600 mg PO bid (with interferon alfa)

*References 33, 43, 263, 504, 505.

resistant.[272] Strains of influenza A virus resistant to amantadine also are resistant to rimantadine, and vice versa, but they are usually susceptible to ribavirin and neuraminidase inhibitors. The mechanism of action against rabies virus appears to be by inhibition of later steps in replication, probably at the level of uncoating, when the virus is released into the intracytoplasmic compartment of infected cells.[520]

Pharmacokinetics

Amantadine is absorbed rapidly and nearly completely after oral administration, with peak plasma concentrations of 0.5 to 0.8 μg/mL attained within 2 hours of administration.[53,230] It is excreted almost unchanged in urine. Nasal and salivary secretions also contain high levels of amantadine, and the drug is present in cerebrospinal fluid (CSF) as well at approximately half the plasma level. Dose reductions, adjusted according to creatinine clearance, are required in patients with renal insufficiency and renal failure.[260,459,569] Rimantadine, on the other hand, is more slowly absorbed than amantadine, with peak plasma levels of 0.4 to 0.6 μg/mL achieved within 2 to 4 hours of administration.[14,230,393] Rimantadine is also present in high concentration in nasal secretions. It is excreted in urine, but only after extensive metabolism by the liver. Dose reduction is therefore recommended in patients with renal or hepatic disease.[79,561] Hemodialysis does not appear to clear either drug, so supplemental doses usually are not recommended after dialysis.[499] When they are administered to chronically ill, institutionalized elderly patients, dosages also may need to be adjusted.[385,416] In addition, aerosolized forms of amantadine and rimantadine have been evaluated in human volunteers.[228,234]

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Amantadine and rimantadine are equally effective for the treatment of disease caused by susceptible subtypes of influenza A virus.[113,313,561] If they are administered within the first 48 hours of symptoms, both agents significantly reduce the signs and symptoms of influenza in both adults and children by significantly shortening the duration of fever and respiratory and systemic symptoms by 1 day.* The duration and amount of viral shedding from the nasopharyngeal tract also are decreased, and otologic complications may be reduced.[139] Both agents are effective for prophylaxis against influenza A virus infection and disease, with approximately 50 percent overall effectiveness in preventing infection with the virus and approximately 60 to 70 percent overall effectiveness (up to 90% in some studies) in preventing clinical disease and, in individuals with breakthrough clinical disease, in reducing the severity of the disease.† The spontaneous emergence of resistant strains during rimantadine or amantadine therapy and subsequent transmission of these resistant strains may lessen the effectiveness of prophylaxis in some families and nursing homes.[222,362] Amantadine and rimantadine are both available as tablets (100 mg) and syrup (50 mg/5 mL) for oral administration.

Emergence of resistance to adamantanes has limited the use of amantadine and rimantadine as single agents for influenza treatment. Since 2005, all circulating H3N2 subtypes of influenza A virus have been resistant to amantadine and rimantadine. Also resistant to adamantanes is the 2009 pandemic subtype influenza A(H1N1)pdm2009, which replaced the previously susceptible seasonal H1N1 subtype when it emerged. Influenza B is intrinsically resistant to the adamantanes. Amantadine has also been included in treatment protocols for patients with rabies encephalitis.[560]

Dosage. The usual dose of amantadine for children is 4.4 to 8.8 mg/kg/day divided twice daily (many experts recommend 5 mg/kg/day), with a maximal recommended daily dose of 200 mg. The usual dose of rimantadine for children is 5 mg/kg/day divided twice daily, with a maximal recommended daily dose of 150 mg.[14,211,393,561] Older children and adolescents may take the usual adult dose for each drug, which is 200 mg/day given once daily or, for better tolerance, divided into two 100-mg doses daily.[14] Elderly patients should receive 100 mg daily or less if renal insufficiency is present. To be effective, these agents should be given as soon as possible after the onset of symptoms.[113,114] The duration of treatment of established influenza should be 3 to 7 days, or at least 2 days after the cessation of systemic signs and symptoms.[113] Prevention of influenza is accomplished best through annual vaccination; however, rimantadine and amantadine may be used to prevent or to lessen influenza symptoms in both adults and children.[101,113,115] Prophylaxis should be administered during the period of risk, whether exposure is in the family, community, or nosocomial setting.[183] In general, prophylaxis should continue for at least 10 days after a known exposure occurs in an unprotected individual.[183] For patients who receive the combination of inactivated vaccine and oral prophylaxis, rimantadine or amantadine should be continued for at least 2 to 4 weeks after vaccination, when maximal antibody response from the vaccine is expected to occur. For patients who are at high risk but did not receive the vaccine, oral prophylaxis should be continued for as long as the period of risk is anticipated and may be extended to the end of the community's influenza season. Doses of both drugs should be adjusted for patients with renal disease, and doses of rimantadine should be adjusted for patients with hepatic disease.[79,260,459,561] Prolonged treatment may be associated with side effects, especially in the elderly.[416] If side effects occur, the daily dose may be reduced to 100 mg and still be effective in most cases. The emergence of resistant strains during the period of drug administration may lessen the effectiveness of prophylaxis in some patients.[222,362] Combination with aerosolized ribavirin or the neuraminidase inhibitors may enhance the antiviral effect of amantadine or rimantadine against influenza A virus.[33,221,259,399,479]

An amantadine dose of 200 mg daily has been used to treat rabies encephalitis.[560]

*References 113, 129, 342, 537, 562, 573.

†References 113, 130, 137, 183, 278, 279, 386, 406, 451, 552, 580.

Adverse Effects. The adverse effects of both amantadine and rimantadine include central nervous system (CNS) effects such as anxiety, depression, insomnia, dizziness, and impaired concentration; in children, these side effects appear to be rare, but they may be manifested as behavioral changes.[101,113,137,496] Rimantadine reportedly has fewer CNS side effects than amantadine does.[113,137,229,380] Hallucinations, tremors, and seizures also may occur, especially in patients with renal failure who have high plasma levels of amantadine. In addition, rare cases of coma and fatal cardiac dysrhythmia have been reported.[423,459] A prudent procedure is to administer amantadine and rimantadine with caution to individuals being treated for seizures or neuropsychiatric disorders or to patients also receiving other medications that affect the nervous system, such as antihistamines.[380] Furthermore, the institutionalized elderly may have increased plasma levels and experience side effects more often than younger patients do.[416] On occasion, gastrointestinal symptoms such as nausea and vomiting may accompany the oral administration of these agents in all age groups. Most reported adverse effects of these two agents have been reversible, with significant long-term complications being exceedingly rare. Of note, amantadine also is used to treat parkinsonism and drug-induced extrapyramidal reactions.[469]

Neuraminidase Inhibitors (Zanamivir, Oseltamivir, Peramivir, and Laninamivir)

Spectrum of Activity

Zanamivir (5-[acetylamino]-4-[(aminoiminomethyl)-amino]-2,6-anhydro-3,4,5-trideoxy-D-glycero-D-galacto-non-2-enoic acid) and oseltamivir ([3*R*,4*R*,5*S*]-4-acetylamino-5-amino-3[1-ethylpropoxy]-1-cyclohexene-1-carboxylic acid ethyl ester phosphate [1:1]) are analogues of *N*-acetylneuraminic acid, the cell surface receptor for influenza viruses, and were designed to inhibit the viral neuraminidase of influenza viruses (Fig. 238-3). Oral oseltamivir and inhaled zanamivir are licensed in the United States. The cyclopentane peramivir ([1*S*,2*S*,3*S*,4*R*]-3-[(1*S*)-1-acetamido-2-ethyl-butyl]-4-(diaminomethylideneamino)-2-hydroxy-cyclopentane-1-carboxylic acid) and laninamivir ([4*S*,5*R*,6*R*]-acetamido-4-carbamimidamido-6-[(1*R*,2*R*)-3-hydroxy-2-methoxypropyl]-5-6-dihydro-4*H*-pyran-2-carboxylic acid) are newer neuraminidase inhibitors currently in clinical trials in the United States.

These four agents are potent and specific inhibitors of the neuraminidases of influenza A (seasonal H3N2, seasonal H1N1, H1N1pdm2009, and avian influenza viruses, including highly pathogenic H5N1 and H9N2) and influenza B viruses. Up to 90 percent of tested strains are inhibited at concentrations of 0.05 to 100 μmol/L.[200,304,539]

Peramivir has also shown efficacy for the treatment of influenza, especially H1N1pdm2009, in at least four efficacy trials.[50] Peramivir, intravenous form, is licensed in Japan and Korea. Peramivir was authorized for emergency use in the United States and other countries for treatment of adults and children with severe influenza during the 2009 H1N1 pandemic. It also was administered through emergency investigational new drug regulations[238] and appeared to be well tolerated and associated with recovery.[238] However, because peramivir under emergency use authorization was limited to critically ill patients for whom other therapy had failed or in whom oral drug absorption was unreliable or inhalation drug not feasible, the efficacy and safety of peramivir could not be adequately assessed.[255] Peramivir has not yet received Food and Drug Administration (FDA) approval in the United States and remains in phase III clinical trials.

Long-acting inhaled laninamivir octanoate is a new neuraminidase inhibitor, with activity against highly pathogenic avian influenza virus H5N1 in addition to influenza A (seasonal H3N2, seasonal H1N1, and H1N1pdm2009) and influenza B.[162,243,469,476] Laninamivir is licensed and available in Japan and in phase III clinical trials in the United States.[273,489,573] Influenza A (AH5N1, AH1N1) and B virus strains with reduced susceptibility to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) have also been detected in hospitalized patients and community-acquired cases of influenza.*

Because influenza virus changes seasonally and antiviral resistance may evolve or emerge suddenly, any statements on presumed spectrum of antiviral activity of any neuraminidase inhibitor should be taken in the context of ongoing viral surveillance.[162,268,276,469,481]

These compounds also are capable of inhibiting neuraminidases from other pathogens and mammalian cells, but only at extremely high concentrations.

*References 34, 162, 243, 256, 268, 269, 270, 271, 273, 509, 521.

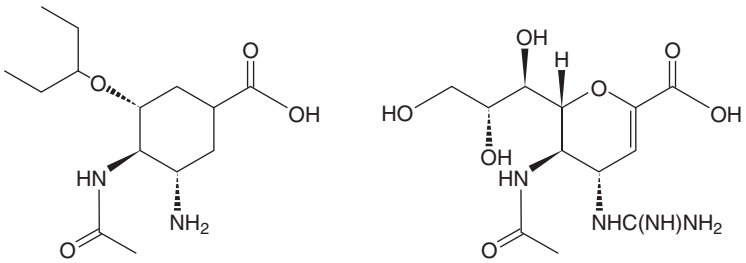

FIGURE 238-3 ■ Structure of the neuraminidase inhibitors oseltamivir and zanamivir.

Mechanism of Action and Resistance

Neuraminidase permits influenza virus to penetrate through the mucoproteins present in respiratory secretions to the surfaces of cells, and inhibition of this enzyme prevents viral access and infection of cells. Neuraminidase also destroys receptors recognized by viral hemagglutinin and is therefore necessary for optimal release of influenza virus particles from infected cells. Inhibition prevents cell-to-cell spread of virus within the respiratory tract and lessens the intensity of the initial infection.[105,113,304,395,539] Mutations that induce amino acid changes in viral neuraminidase alter enzyme stability or activity, mutations in hemagglutinin produce a reduced affinity for cell receptors, and mutations in both produce resistant influenza viruses.[113,202-205] Cross-resistance to both zanamivir and oseltamivir, as well as to oseltamivir and peramivir, also can occur, especially if the mutation is in the hemagglutinin portion.[375] Resistance occurs either by spontaneous mutation or by selection during antiviral treatment and has been documented by in vitro passage of the virus in increasing concentrations of the agents, in patients receiving these antiviral agents, and in newly emerged strains that acquire a change in neuraminidase through mutation or reassortment. In 2007, influenza A(H1N1) seasonal acquired a change in neuraminidase, designated H275Y, that resulted in oseltamivir resistance, but zanamivir susceptibility was retained. In 2009, oseltamivir-susceptible influenza A(H1N1) pdm2009 emerged, replacing the oseltamivir-resistant seasonal H1N1. Beginning in 2009, individual cases of oseltamivir resistance, usually in immunocompromised patients receiving treatment, as well as community clusters of oseltamivir-resistant influenza A(H1N1)pdm2009 began to be detected.[84,145] Sporadic oseltamivir resistance has also been detected in avian influenza A(H5N1). Clinical trials of oral oseltamivir for the treatment of naturally occurring influenza detected resistance in 1 to 2 percent of post-treatment isolates from adults and adolescents and in 5 to 8 percent of isolates from younger children.[113,204,260,576] Currently, most seasonal H1N1 strains circulating in 2008-2009 were resistant to oseltamivir, and the overall occurrence of influenza A H1N1 subtypes resistant to oseltamivir is estimated at a rate of 2.6 percent, with an association between oseltamivir resistance and pneumonia in four clinical studies.[34,235,270,273,529]

Peramivir resistance has also been documented in both influenza A, including pandemic A(H1N1)pdm2009, and influenza B.[413] A point mutation at H273Y in one influenza B isolate from a human patient conferred double resistance to both oseltamivir and peramivir.[243] Most peramivir- and oseltamivir-resistant influenza strains remain susceptible to zanamivir at this time.

Zanamivir resistance appears rare, documented in case reports of either influenza A or B virus infection in patients who were usually immunocompromised hosts receiving antiviral medications for prolonged periods.* Large randomized trials of healthy individuals have not documented zanamivir resistance, but individualized case reports and small case series have shown that zanamivir resistance has emerged.[202,227,231,236,382] In one study from Australia, analysis of 391 influenza A(H1N1) seasonal isolates documented zanamivir resistance in 9 (2.3%) isolates.[271] Influenza B viruses with mutations in the neuraminidase active site conferring resistance to oseltamivir, peramivir, and zanamivir have been reported from several geographic sites.[162,243,469,481] Overall, there are currently at least 50 different documented amino acid substitutions that have produced mutations conferring reduced antiviral susceptibility to oseltamivir, zanamivir, peramivir, or laninamivir in influenza A and B viruses.[402,403] Preliminary evidence suggested that some mutant resistant strains may have reduced infectivity or virulence in comparison to susceptible strains,[524] but resistant strains have caused outbreaks and epidemics.[235] Therefore, difference in influenza virulence cannot be predicted by the antiviral susceptibility pattern of the strain.

*References 202, 206, 227, 231, 236, 382, 529.

Pharmacokinetics

Zanamivir is administered as an inhaled dry powder and is deposited in the oropharynx and, to a lesser extent, in the tracheobronchial tree and lungs.[113] Approximately 4 to 17 percent of inhaled drug is absorbed systemically, and levels of 17 to 142 ng/mL can be detected in serum 1 to 2 hours after administration of a typical inhaled dose of 10 mg to adults.[80] Serum levels in pediatric patients who received an inhaled dose were extremely low (<10 ng/mL) or undetectable, which may be related to the ability of the patient to cooperate with the inhaled drug delivery system. The oral bioavailability of zanamivir is extremely low, with less than 5 percent of the administered dose absorbed, and therefore it is not administered in this form. Intravenous and intramuscular preparations of zanamivir also have been tested in clinical trials, but this form is not available clinically at this time.[78,80,180,235] Intravenous zanamivir provides a sustained antiviral effect.[175] It also penetrates lung tissue. Zanamivir administered intravenously at doses of 100 mg, 200 mg, and 600 mg provides concentrations in epithelial lung fluid 12 hours after dosing of 74, 146, and 419 ng/mL, respectively.[476] In contrast, inhaled zanamivir concentrations provide much higher levels of 396 to 891 ng/mL to the respiratory tract. Zanamivir is not metabolized, and approximately 90% of zanamivir is excreted unchanged in urine.[80]

Oseltamivir, in contrast, has good oral bioavailability. The prodrug compound oseltamivir phosphate is metabolized by hepatic esterases to the parent active compound oseltamivir carboxylate.[113] Approximately 75 to 80 percent of the administered dose is absorbed, and peak plasma concentrations are reached within 3 to 4 hours but may be delayed, but not reduced, if the drug is given with food. A typical 75-mg dose will provide plasma concentrations of 0.3 to 0.5 μg/mL. Both the prodrug and the active form are eliminated unchanged through the kidneys, and dosages should be adjusted for patients with renal insufficiency or renal failure. Whether the drug dosage should be adjusted for patients with hepatic disease or liver failure is unclear from the available evidence. Information from a small number of pediatric patients suggests that the drug may be eliminated faster

in younger children. Elderly, geriatric patients, however, appear to metabolize the drug similar to young adults.

Peramivir administered orally in doses ranging from 100 to 800 mg daily is not well absorbed and produces only modest antiviral effect.[37] Peramivir has been administered intravenously in doses of 200, 400, and 600 mg daily, or approximately 4 to 10 mg/kg once daily.[274] Plasma concentration of approximately 20 ng/mL within 24 hours of infusion has been documented, which is far in excess of the reported IC_{50} of peramivir against susceptible influenza strains. Pediatric dosing for peramivir suggests that 10 mg/kg daily produces adequate plasma levels and good antiviral effect with few adverse effects.[477] Pregnant or postpartum women may require higher doses on the basis of limited pharmacokinetic studies that have demonstrated increased plasma volume, increased volume of distribution of peramivir, and shorter half-life.[100] The half-life of peramivir varies between 7 and 20 hours in patients with normal renal function. Peramivir is excreted in the urine as the unchanged form, and dosage adjustments are needed in renal impairment. Patients with proven influenza infection show antiviral effects with decreased viral shedding between days 2 and 6 of treatment (7% to 20%), with clinical improvement and recovery.[477]

Laninamivir octanoate is the prodrug of the active compound laninamivir. It is administered as a single inhalation of either 20 mg or 40 mg to treat influenza infection. It is retained in the tissues and eliminated from the body very slowly, with a plasma half-life of 2 hours and lasting at least 3 days. Urinary excretion appears to occur. Clinical trials show that one inhalation of laninamivir is an effective and well-tolerated treatment for children and adults with seasonal influenza, including oseltamivir-sensitive and oseltamivir-resistant influenza A(H1N1) virus infection.[476,549]

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Zanamivir and oseltamivir have been shown to be effective in treating both influenza A and influenza B infection.[77,288,363,548,549] However, susceptibility of type B and H5NI and H1N1 subtypes of type A influenza may be reduced for oseltamivir.[520] When they are administered within the first 2 days of illness, they provide relief from symptoms up to 1.5 days earlier than placebo does and reduce the quantity and duration of viral shedding.* In some studies, the frequency of secondary complications, such as sinusitis, bronchitis, and otitis media with effusion (but not pneumonia), also was reduced.[113,544] Both antiviral agents are effective for the prophylaxis of influenza A and influenza B infection in both adults and children in family, community, transplant recipient, and nursing home situations.[276] They appear to be 30 to 50 percent effective in preventing viral infection and 64 to 84 percent effective in preventing disease.† However, up to 89 percent efficacy in preventing disease in families has been reported, and in elderly patients in nursing homes, 92 percent of cases of influenza may be prevented if the agents are administered to those who also have received influenza vaccine.[113,227,366] Oseltamivir may be administered to a patient of any age to treat influenza.

Peramivir may be administered intravenously, under investigational or emergency investigational new drug or clinical trials, to patients unable to tolerate oral oseltamivir or inhaled zanamivir.[347,451] The temporary emergency use authorization for peramivir for treatment of 2009 H1N1 influenza, granted by the FDA and managed through the Centers for Disease Control and Prevention, terminated in June 2010.[50,238] On the basis of results of clinical trials and experience with the emergency use authorization, 300- to 600-mg doses of peramivir appear to be effective for treatment of high-risk patients infected with susceptible influenza A or B virus strains.[50,238,316] Peramivir probably should not be used to treat patients with oseltamivir-resistant influenza infection (H275Y mutation), patients with mutations of neuraminidase E119D or R292K (which confer peramivir resistance), or patients suspected of having influenza caused by zanamivir resistance because it is likely not to be effective.

Laninamivir may be administered in some countries as a single inhalation to treat influenza A H1N1 and H5N1 infections in adults and children. A dose of laninamivir, 20 to 40 mg, administered in a single inhalation, is retained in the respiratory tissues for a prolonged time, providing very high levels, in excess of the IC_{50} of susceptible influenza strains. This high level may reduce the risk of emergence of resistant strains. Inhaled or intranasal laninamivir also enters the plasma, and renal excretion correlates with creatinine clearance. Pharmacokinetic studies suggest that dose adjustment may be necessary only in severe renal insufficiency.[274,549]

Intravenous zanamivir, which remains investigational at this time, appears effective in treating high-risk, critically ill patients, including immunocompromised patients, with oseltamivir- or peramivir-resistant influenza A infection.[145,175,189,276,413]

Dosage. Zanamivir is administered by oral inhalation with an inhalation device provided with the product. Each inhalation dose is 5 mg, and two inhalations twice daily for 5 days is the usual recommended dosage for all age groups. Use of this drug and device is dependent on the understanding and cooperation of the patient; therefore, it is not indicated for use in children younger than 7 years and may be of limited use in older children and adults who are unable to cooperate with the delivery system. No reduction in dosage is needed for patients with impaired renal function because very little of the inhaled drug is absorbed systemically.

Zanamivir has also been administered by nebulizer at a dosage of 16 to 32 mg (usually 24 mg) in 1 to 2 mL of sterile water every 6 hours for 5 to 10 days.[206]

Zanamivir has been administered intravenously in doses of 600 mg at a constant rate during 30 minutes, every 12 hours for 5 days, under investigational, compassionate use to individual patients and currently is being

*References 77, 113, 231, 313, 366, 382, 388, 426, 533, 553.
†References 113, 227, 233, 366, 387, 544.

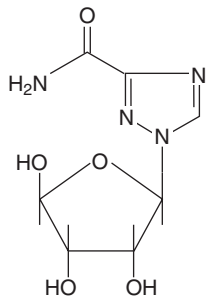
evaluated in clinical trials (www.clinicaltrials.gov).[136,145,219] Pediatric dosing in the clinical trials is weight based and age adjusted. A dose of 4 to 10 mg/kg per dose every 12 hours has been evaluated.[144] Younger children appear to require higher doses; children who weigh less than 11 kg may be given up to 24 mg per dose if renal function is normal. Some institutions have administered up to 16 to 24 mg/kg per dose every 12 hours. All trials agree that a maximum of 600 mg/dose should be given twice daily, and this maximum dose should be used for children who are older than 13 years or weigh more than 37 kg and have normal renal function. Doses should be adjusted in renal impairment according to creatinine clearance.

Oseltamivir is administered orally and is available in 75-mg capsules and a 12-mg/mL suspension. The usual adult dosage is 75 mg twice daily for treatment and once or twice daily for as long as 6 weeks for prophylaxis. The pediatric dose is 2 mg/kg per dose given twice daily (4 mg/kg/day divided twice daily).[113] Double dosing of oral oseltamivir (up to 150 mg twice daily for adults and older children) was recommended for some patients during the 2009 H1N1 influenza A pandemic and may be used for treatment of severe seasonal or pandemic influenza or influenza caused by a strain thought to have reduced susceptibility to oseltamvir.[100]

Peramivir has been administered intravenously to adults in doses between 300 and 600 mg once daily, during a 60-minute infusion.[497,574] Weight-based dosing suggests a once-daily dose of approximately 4 to 10 mg/kg. Duration of treatment is recommended for 5 to 10 days.[274,275] Pediatric dosing, for ages 3 months to 15 years, has been studied. A once-daily dose of 10 mg/kg, with a maximum daily dose of 600 mg, appears to be clinically and virologically effective and safe in infants and children with influenza.[477,517] Neonates should be dosed at 6 mg/kg daily and infants at 8 to 10 mg/kg daily, according to FDA guidance (www.fda.gov). Dosage adjustments are needed in renal impairment. Patients with severe or end-stage renal disease should probably receive 100 mg daily and after each dialysis because peramivir is cleared by dialysis (www.fda.gov).

The dose of laninamivir is 20 to 40 mg, administered in a single inhalation to treat the entire illness. Dosage adjustments are necessary only in severe renal impairment.[274,516,549]

Adverse Effects. Both neuraminidase inhibitors are generally well tolerated, with few if any serious adverse effects observed in clinical trials. Zanamivir inhalation, however, may produce local irritation or bronchospasm in some patients, and oseltamivir has been associated with nausea and vomiting, which may be lessened by administration of the drug with food.[113] The most commonly observed side effect of inhaled laninamivir is gastrointestinal. The most common side effects of intravenous peramivir are nausea, vomiting, diarrhea, and neutropenia. Rarely, skin reactions and anaphylaxis have occurred with peramivir administration. Intravenous zanamivir appears well tolerated on the basis of limited clinical experience at this time.



Ribavirin

FIGURE 238-4 ■ Structure of ribavirin.

Ribavirin

Spectrum of Activity

Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) is a synthetic guanosine analogue with broad-spectrum antiviral activity (Fig. 238-4).[487] It inhibits the in vitro replication of a wide variety of RNA viruses, including orthomyxoviruses such as influenza A and B viruses; paramyxoviruses, such as RSV, parainfluenza viruses, and measles virus; arenaviruses, such as Lassa fever virus; bunyaviruses, which cause viral encephalitis; togaviruses, such as HCV; enteroviruses, such as enterovirus 71, polioviruses, and coxsackie B virus; rabies virus; and retroviruses, including human immunodeficiency virus (HIV) type 1.* Also inhibited by ribavirin are many DNA viruses, such as adenoviruses, hepatitis A virus, cytomegalovirus (CMV), and poxviruses (e.g., vaccinia virus).[138] It inhibits most orthomyxoviruses and paramyxoviruses at concentrations of 3 to 10 μg/mL and Lassa fever virus at 4 to 40 μmol/L.[266] Because most of its clinical use has been for the treatment of RNA viruses, ribavirin is included in this section of the chapter.

Mechanism of Action and Resistance

Ribavirin most likely exerts its antiviral effects by altering the cellular nucleotide pools and by interfering with viral mRNA formation.[71,160,511] The compound is phosphorylated by host cell enzymes to monophosphate, diphosphate, and triphosphate active forms, each with specific antiviral actions.[525] For example, ribavirin monophosphate competitively interferes with the synthesis of guanosine triphosphate and, subsequently, with viral nucleic acid synthesis. Ribavirin triphosphate inhibits the RNA polymerase of influenza virus and also interferes with the capping of its viral mRNA.[160,302,408,558,568] In addition, the diphosphate and triphosphate forms of ribavirin appear to inhibit the reverse transcriptase activity of HIV-1.[166] The mechanism of action of ribavirin against HCV and other viruses, however, is not well understood. Ribavirin also exerts an effect on the host immune system by inhibiting mast cell secretory responses and diminishing IgE responses.[443] Antiviral resistance is not well characterized

*References 160, 263, 302, 328, 330, 340, 408, 478, 560.

and appears to be a rare occurrence. No ribavirin-resistant RSV isolates have been identified during clinical trials, and information is scant regarding the resistance of other viruses to ribavirin.[213,350,464]

Pharmacokinetics

Ribavirin can be administered by aerosol, orally, and intravenously. Aerosol administration of ribavirin with a small-particle aerosol generator delivers very high concentrations (>1000 μg/mL) of the drug to the respiratory tract.[315] Aerosolized drug also is absorbed systemically, and peak plasma levels after 8 hours of continuous aerosol administration range from 0.5 to 2.2 μg/mL; after 20 hours, they reach 0.8 to 3.3 μg/mL. After oral administration, bioavailability is 33 to 45 percent, and peak plasma levels of 1.3 to 3.2 μg/mL have been observed 1 to 2 hours after administration. Intravenous administration of ribavirin produces 10-fold higher plasma levels in less than 1 hour than after the administration of equivalent doses by different routes.[414] Higher doses used to treat Lassa fever produce plasma levels of up to 24 μg/mL. Ribavirin also crosses the blood-brain barrier and is present in CSF at approximately 70 percent of the plasma level.[110,261] The drug is metabolized by the liver, and approximately 40 percent of the dose is excreted by the kidneys.[414] The triphosphate form also concentrates in erythrocytes at an erythrocyte-to-plasma ratio of 40:1 and is slowly eliminated with a half-life of 40 days or longer. Hemodialysis and hemofiltration do not remove significant amounts of ribavirin from the body.[319]

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Ribavirin aerosol is licensed for the treatment of RSV bronchiolitis and pneumonia in children.[210] Treatment shortens the duration of viral shedding and improves the fever, respiratory rate, arterial oxygen saturation, and lower respiratory tract signs on physical examination in severely ill patients who receive the antiviral agent early in the course of their illness.*

No clear benefit has been observed in patients with mild disease or in those who receive treatment late in the course of the disease. Studies of infants receiving mechanical ventilation have reported conflicting results in clinical benefit.[372,383,488] However, despite numerous clinical studies, indications for treatment remain controversial because efficacy has not been documented convincingly in all studies and the benefits observed generally have been mild and difficult to quantitate objectively.[210] Nonetheless, because antiviral treatment clearly appeared to provide benefit to some children, in 1996, the American Academy of Pediatrics recommended that ribavirin be considered for the treatment of hospitalized infants and children with severe lower respiratory tract infection caused by RSV. Currently, the American Academy of Pediatrics recommends that ribavirin may be considered for use in selected patients with documented, potentially life-threatening RSV infection.[9]

*References 201, 212, 240, 285, 372, 383, 430, 485, 488, 554.

Patients thought to potentially benefit the most from inhaled ribavirin treatment are those younger than 6 weeks; those with chronic illnesses, such as congenital heart disease and chronic lung disease; premature infants; immunosuppressed children with primary immune disorders or those undergoing marrow or solid-organ transplantation; and those with neurologic or neuromuscular disorders.[474] Treatment with ribavirin also appears to decrease nasopharyngeal secretion of RSV-specific IgE and IgA responses.[449] Long-term follow-up of treated patients suggests no adverse effects but possible improvement in pulmonary function.[240,285,346] Treatment may benefit immunocompromised children who have serious or prolonged RSV infection, such as those with congenital severe combined immunodeficiency.[369] Aerosolized or intravenous ribavirin, especially combined with intravenous immune globulin or RSV hyperimmune globulin, also may be of benefit to bone marrow transplant recipients and solid-organ transplant recipients with RSV lower tract disease.* Intravenous administration appears less costly than aerosolized treatments.[123,194,384] Anecdotal reports suggest that early administration of ribavirin to immunocompromised patients during upper respiratory tract disease may be more efficacious than supportive care alone in preventing progression to lower tract disease or pneumonia.[156,369] Some centers have used oral ribavirin therapy for RSV infection, instead of inhaled or intravenous administration. Small studies have shown similar therapeutic outcomes between oral and inhaled ribavirin therapy for RSV infection and lower respiratory tract disease after solid-organ transplantation.[339,417] Laboratory confirmation of RSV infection by viral culture or rapid diagnostic tests that detect viral antigen in respiratory secretions is recommended for all patients before treatment with ribavirin is initiated or continued beyond 12 to 24 hours. Ribavirin also is licensed in capsule form for the treatment of chronic hepatitis caused by HCV, and in combination with interferon alfa, it produces a sustained decrease in HCV RNA levels, improvement in systemic symptoms such as fatigue, reduction in transaminases, and improvement in liver histologic features. These clinical benefits have been observed during initial treatment in previously untreated patients, in individuals initially unresponsive to interferon alone, and in patients treated for relapse.† Treatment with high doses of orally or intravenously administered ribavirin significantly reduces mortality rates in patients with Lassa fever.[66,284,367] Ribavirin also appears to benefit patients suffering from other hemorrhagic fever syndromes, including Argentine, Sabiá, Bolivian, and Crimean-Congo hemorrhagic fevers, as well as those who have hemorrhagic fever with renal failure syndrome.[158,169,264,265,303] Ribavirin has also been used to treat La Crosse encephalitis, but clinical trials have not shown a clear therapeutic benefit.[370] In addition, ribavirin may benefit patients with other causes of viral encephalitis, including rabies, but clinical trials have not been performed.[81] Oral ribavirin also may be of benefit prophylactically in individuals who are exposed to

*References 123, 194, 346, 349, 384, 555.
†References 52, 55, 125, 134, 179, 262, 368, 436.

hemorrhagic fever syndromes, including Lassa fever.[257] Treatment of hantavirus pulmonary syndrome with intravenously administered ribavirin is being evaluated in clinical trials.

Ribavirin may benefit individuals with influenza A or B virus infection. In one randomized study of young adults suffering from influenza, aerosol treatment significantly reduced fever, systemic signs and symptoms, and virus titer in respiratory secretions.[487] Another study showed clinical benefit with high-dose oral ribavirin, but other studies have not confirmed a measurable clinical benefit or virologic response consistently with aerosolized or oral ribavirin.[47,314,467,487,507] Intravenous ribavirin also has been used anecdotally to treat serious, life-threatening influenza.[232,432] Early treatment with aerosolized or intravenous ribavirin in bone marrow and stem cell transplant recipients infected with parainfluenza virus may help prevent progression to lower tract disease and pneumonia or treat viremia and myocarditis, but controlled trials documenting efficacy and effect on overall mortality rates have not been published.[152,232,291,553] Ribavirin also has been used to treat measles pneumonia in immunocompetent and immunocompromised patients, with clinical benefit reported in some.[172,207,292] Ribavirin has also been included in treatment protocols for patients with rabies encephalitis.[353,560]

Clinical benefit, but not cure, also has been documented in case reports of children with subacute sclerosing panencephalitis caused by measles virus.[261,262,392,485] In these reports, repeated courses of large doses of ribavirin administered intravenously, combined with interferon alfa, provided serum and CSF levels that exceeded the minimal inhibitory concentrations needed to inhibit the virus in vitro and improved or stabilized seizures and neurologic status in treated patients.[261] Case reports and small series using ribavirin to treat serious adenoviral disease, including pneumonia and disseminated adenoviral disease, have been published, but no controlled trials documenting clinical benefit have been published.* Despite documented antiretroviral activity, treatment of HIV-infected patients with oral ribavirin has not shown clinical, virologic, or immunologic benefits consistently.[110,166,286]

Dosage. A number of different dosages and routes of administration have been used to administer ribavirin to a variety of patients experiencing various infections. In normal and immunocompromised patients of all ages, the usual dosage of ribavirin, when it is administered topically by aerosol to the respiratory tract for treatment of influenza and lower respiratory tract disease caused by RSV, parainfluenza virus, and measles virus, is 6 g of drug reconstituted in a final volume of 300 mL of sterile water (final concentration, 20 mg/mL); a small-particle aerosol generator (SPAG-2 unit) is used to administer the drug continuously during a period of 12 to 18 hours for 3 to 7 days.† The drug may be delivered to an infant oxygen hood or tent, by facemask, or through pressure- or volume-cycled ventilators, provided ventilatory pressure is monitored and the device is checked for precipitation, which may cause ventilator dysfunction.[178,407]

Intermittent high-dose therapy, with drug administered at 60 mg/mL for 2 hours three times daily for 5 days, also appears to be effective and may be better tolerated in some older patients.[155] Longer courses of aerosolized therapy for up to 14 days have been used in severely immunocompromised patients with prolonged viral shedding and severe disease.[338] Oral doses of up to 600 mg twice daily for 24 to 48 weeks, usually combined with interferon alfa, are used to treat hepatitis C in adults.* High doses of oral ribavirin also appear to be effective in treating influenza in normal hosts and RSV infection in immunocompromised hosts.[340,417,474] Even higher doses of oral ribavirin (2-g loading dose, followed by 2 g/day divided every 8 hours for 10 days) have been used for the treatment of Lassa fever and other hemorrhagic fever syndromes in adults.† The intravenous dose of ribavirin used to treat Lassa fever is a 2-g loading dose (25 to 33 mg/kg estimated pediatric dose), followed by 1-g doses (16 mg/kg estimated pediatric dose) every 6 hours for 4 days and then 500-mg doses (8 mg/kg estimated pediatric dose) every 8 hours for 3 days to complete a 7- to 10-day course of treatment.[284,367] This intravenous dosage regimen also has been used to treat measles pneumonia, severe influenza with complications, pneumonia caused by RSV and parainfluenza virus in immunocompromised patients, and disseminated adenovirus disease.[172,207,349,432] Continuous intravenous infusions of ribavirin have been used in patients with severe disease caused by influenza and parainfluenza viruses.[232] Doses used to treat subacute sclerosing panencephalitis in children have been considerably higher and administered for longer periods.[261,392] In one report, pediatric patients received interferon alfa combined with 10 mg/kg of ribavirin administered intravenously every 8 hours daily for 7 days. Escalating doses of 20 mg/kg and then 30 mg/kg given every 8 hours daily for 7 days at 7-day intervals then were administered.[261] The highest dose tolerated was given for 7 days, repeated in 7-day intervals, and administered for a period of 6 months.

Adverse Effects. Adverse effects of aerosolized ribavirin are unusual but include local irritation causing facial rash and conjunctivitis. Abnormalities in pulmonary function, including worsening of respiratory distress and bronchospasm, also have been reported.[193,213,483] In addition, one case of water intoxication associated with aerosolized ribavirin administration has been reported.[530] Older children, adolescents, and adults may be noncompliant with treatment or may even have anxiety attacks or experience other forms of psychological stress as they are being confined for continuous treatment for a 12- to 18-hour period. In these cases, intermittent, high-dose regimens may be better tolerated and might enhance compliance of the patient.[155] Precipitation of the drug in ventilator tubing systems and on filtering devices may

*References 31, 61, 86, 187, 361, 390.
†References 47, 152, 201, 212, 213, 292, 314, 338, 361, 372, 383, 390, 487, 488, 523, 555.

*References 52, 55, 125, 134, 258, 368, 436.
†References 158, 169, 257, 265, 284, 303, 367.

cause ventilator dysfunction and respiratory distress or failure in mechanically ventilated patients, especially those receiving high-dose intermittent administration, but such events may be minimized by frequent monitoring of ventilator pressure and changing of the filters.[178,372,383,407] Adverse hematologic effects, such as anemia, have not been documented consistently in patients who received aerosolized ribavirin. The environmental exposure to aerosolized ribavirin by health care workers providing direct care to a virus-infected patient may, in some instances, cause headache, conjunctivitis, contact lens damage, watery eyes, and bronchospasm in those with underlying reactive airway disease.[64,193,443,477]

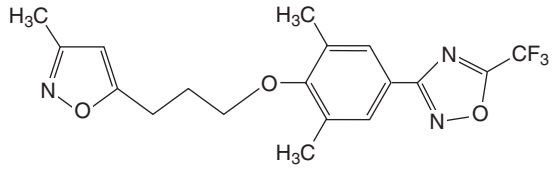
These potential adverse effects are probably more likely to be seen in instances in which ribavirin is administered by hood, tent, or facemask than when it is administered to mechanically ventilated patients.[65] Environmental exposure of health care workers and family members may be reduced by providing routine patient care during periods when the aerosol generator has been turned off, by turning off the aerosol generator during periods of more urgent care, and by using protective equipment such as masks and goggles. Dose-related, reversible, usually mild anemia occurs frequently during and after long-term oral therapy and intravenous administration of ribavirin.[258,286,369] Rarely, severe anemia may occur and necessitate dose reduction or cessation of therapy.[370] Reversible increases in serum bilirubin, serum iron, and uric acid concentrations also have been documented during oral therapy. On rare occasion, intravenous administration of ribavirin has produced chills and rigors.[168,193]

Ribavirin has shown teratogenic, mutagenic, and embryotoxic effects in preclinical animal models.[247] Therefore, investigators recommend that exposure of pregnant women to ribavirin, either therapeutically or through environmental exposure, be minimized or prevented whenever possible or practical.

Pleconaril

Spectrum of Activity

Pleconaril (3-[3,5-dimethyl-4[[3-(3-methyl-5-isoxazolyl) propyl]oly]phenyl]-5-(trifluoromethyl)-1,2,4-oxadiazole) is an antiviral agent with significant and specific activity against picornaviruses, both enteroviruses and rhinoviruses (Fig. 238-5). In vitro, pleconaril inhibits the replication of most serotypes of enteroviruses at concentrations between 0.01 and 0.1 μg/mL. Echovirus 11, a commonly isolated enterovirus in the United States, appears to be the most sensitive enterovirus tested to date (inhibited at a mean concentration of 0.006 μg/mL), although resistant strains have been reported. Most rhinovirus serotypes are inhibited at slightly higher concentrations of 0.21 to 0.78 mg/mL but still within ranges safely achievable in patients.



Pleconaril

FIGURE 238-5 ■ Structure of pleconaril.

Mechanism of Action and Resistance

Pleconaril binds efficiently to a specific hydrophobic pocket within the viral capsid of picornaviruses and exhibits an antiviral effect by interfering with uncoating, attachment, and cell-to-cell transmission of infectious viral particles.[450] The drug induces a more rigid structure within the viral capsid, which then interferes with viral uncoating and release of viral RNA.* Pleconaril also appears to change the conformation of the canyon floor of the virus capsid when it integrates with the underlying pocket, thereby interfering with attachment of the virus to host cell receptors.[420,421] Resistance of picornaviruses to pleconaril has been reported.

Pharmacokinetics

The pharmacokinetics of pleconaril varies with the age of the group tested. After oral administration of single doses of 200 to 400 mg to adults, peak plasma concentrations of 1.1 to 2.4 μg/mL are achieved in 1.5 to 5 hours, with an average elimination half-life of 25 hours.[2] Repeated dosing for a 7-day period increases plasma concentrations to 1.33 to 3.4 μg/mL. When pleconaril is taken with food, especially a meal high in fat, absorption is enhanced significantly.[1,298] Single oral doses of 5 mg/kg in children provide plasma concentrations of approximately 1.3 μg/mL with a more rapid elimination half-life of approximately 6 hours.[297] Neonates also absorb pleconaril well, but they do not exhibit dose-proportionate pharmacokinetics as adults do.[298] The drug also has a large volume of distribution and concentrates in tissues such as the liver, brain, and nasal epithelium, where viral replication and virus-induced disease are likely to occur.[298] Pleconaril appears to be excreted in feces and urine.

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Pleconaril currently is not licensed for therapeutic use, and it is not available at this time for compassionate use.[559] However, clinical trials continue to evaluate pleconaril for treatment of serious enteroviral disease as well as rhinovirus infection in neonates and children (www.clinicaltrials.gov). Pleconaril has shown efficacy in early clinical trials against picornavirus infections in adults, children, and neonates. In pretreated adults experimentally infected with coxsackie A21 virus, pleconaril significantly reduced viral titers as well as the clinical parameters of fever, nasal mucus production, and systemic symptoms compared with placebo.[223,450,465] In

*References 174, 371, 420, 421, 444, 450.

another trial, pleconaril resolved the symptoms of illness 2 days earlier than placebo did, and patients who received pleconaril did not require as much concomitant medication for symptomatic relief as did those who received placebo.[450] In two placebo-controlled trials in adults with aseptic meningitis caused by enterovirus, pleconaril treatment reduced the duration of headache and other symptoms of meningitis by 2 to 3 days and allowed treated patients to return to work and routine daily activities 2 days earlier than patients who received placebo.[450,465] In a placebo-controlled trial in pediatric patients with aseptic meningitis caused by enterovirus, pleconaril significantly improved illness scores and reduced the duration of headache in older children, but clinical efficacy was difficult to assess in infants and younger children.[3] Viral shedding from the throat also was reduced in the treatment group.[460]

In addition to treatment of the "common cold" and "viral meningitis," another potential use of pleconaril is for the treatment of serious, persistent, or life-threatening illness caused by enteroviruses. More than 90 patients with unusual or life-threatening infections with enterovirus have received pleconaril on a compassionate-use basis.[174,559] These patients included immunocompromised patients with chronic meningitis, neonates with disseminated disease, patients with myocarditis,[450,559] and individuals with poliomyelitis associated with vaccine or wild-type poliovirus.[445] In all groups, most of the patients showed clinical and virologic responses.

Dosage. Pleconaril is manufactured as a hard gelatin capsule and an oral solution. A nasal spray formulation has also been developed and tested in clinical trials against rhinovirus infection. The capsule contains 200 mg of drug, and doses used in adults and older children have been 200 to 400 mg every 8 hours for 7 days (21 doses). An oral solution also has been prepared for pediatric use. It contains 40 mg/mL of pleconaril, medium-chain triglycerides, two surfactants (Tween 80 and Arlacel), 1.5 percent saccharin, and cherry-peppermint flavoring. Doses of 5 mg/kg, 7.5 mg/kg, and 8 mg/kg of the oral solution administered every 8 to 12 hours for 7 days (14 to 21 doses) have been used in clinical trials of young children, infants, and neonates.[450] Oral pleconaril is generally well tolerated by all age groups.

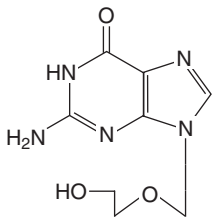
Adverse Effects. Adverse effects associated with pleconaril treatment include nausea, diarrhea, stomach upset or discomfort, and headache. Serious toxicities have not been documented to date, and preclinical studies did not show teratogenicity or fetal toxicity.

ANTIVIRAL AGENTS ACTIVE AGAINST DNA VIRUSES (Table 238-3)

Acyclovir

Spectrum of Activity

Acyclovir, 9-[(2-hydroxyethoxy)methyl]-9*H*-guanine (also known as acycloguanosine), is an analogue of the nucleoside deoxyguanosine that has selective activity against the herpes family of viruses (Fig. 238-6).[120,151] It has the most potent antiviral activity against HSV type 1 and inhibits the virus at concentrations of 0.02 to 0.9 μg/mL.[542,557] Inhibitory concentrations of HSV type 2 and VZV are also high, at 0.3 to 2.2 μg/mL and 0.8 to 4.0 μg/mL, respectively.[51,503,542,557] In addition, EBV replication is inhibited by acyclovir at a mean concentration of 1.6 μg/mL, but the drug has no effect on cells latently infected with EBV.[103,241,519] CMV also is inhibited by very high concentrations of acyclovir (2 to 57 μg/mL).[51] Acyclovir has in vitro activity against simian herpesvirus B and hepatitis B virus (HBV).[46,260,542]



Acyclovir

FIGURE 238-6 ■ Structure of acyclovir.

Mechanism of Action and Resistance

Acyclovir is phosphorylated to acyclovir monophosphate by viral TK. Cellular enzymes then convert the monophosphate form to acyclovir triphosphate, the active form of the drug.[557] Acyclovir triphosphate is present in HSV-infected cells at 40 to 100 times the concentration found in uninfected cells, and it competitively inhibits viral DNA polymerase in infected cells. Acyclovir triphosphate also is incorporated into viral DNA and, because it lacks the 3′-hydroxyl group, acts as a chain terminator during viral DNA synthesis. The DNA polymerase enzymes of the various herpesviruses differ in their degree of inhibition by acyclovir triphosphate, and for EBV and CMV, which do not contain viral TK, this inhibition accounts for most of the antiviral effect of the drug.[131,181] Host cellular growth also can be inhibited by acyclovir, but only at levels thousands of times higher than those that inhibit viral replication. This relatively selective mechanism of antiviral action provides a uniquely high therapeutic index.

Three basic mechanisms of resistance have been identified for herpesviruses to become resistant to acyclovir: deficient TK activity caused by absent or low production of viral TK, altered TK activity caused by abnormal substrate specificity so that the enzyme is present and able to phosphorylate but just does not phosphorylate acyclovir, and altered DNA polymerase.[87] Most clinical isolates of HSV that are resistant to acyclovir have deficient TK activity, and most resistant VZV isolates have altered TK activity or altered DNA polymerase.[415,526] The prevalence of acyclovir-resistant HSV isolates in normal hosts is less than 1 percent, but it can be as high as 10 to 20 percent in immunocompromised hosts receiving acyclovir therapy

TABLE 238-3 **Clinical Indications and Usual Treatment Dosages for Antiviral Agents Active Against DNA Viruses**

Agent	Indication	Dosage
Acyclovir	HSV, mucocutaneous	5% ointment 6× daily
		15 mg/kg/dose PO 5× daily (max, 200 mg/dose)
		5-10 mg/kg/dose IV q8h
	HSV, encephalitis	10-20 mg/kg/dose IV q8h
	HSV, neonatal	20 mg/kg/dose IV q8h
	VZV, chickenpox and zoster	20 mg/kg/dose (max, 800 mg) PO q6h
		10-20 mg/kg/dose (500 mg/m^2/dose) IV q8h
Valacyclovir	HSV	500-1000 mg/dose PO bid
	VZV, zoster	1000 mg/dose PO bid
Penciclovir	HSV, mucocutaneous	1% cream q2h
Famciclovir	HSV, mucocutaneous	125-500 mg PO bid
	VZV, zoster	500 mg PO tid
Ganciclovir	CMV	5-6 mg/kg/dose IV q12h—induction
		5 mg/kg/dose qd 5 days/wk
		or
		1000 mg PO tid
		or
		500 mg PO 6× daily—maintenance
Valganciclovir	CMV	900 mg PO bid—induction
		900 mg PO qd—maintenance
		15 to 18 mg/kg/dose every 12 hours or BID
Foscarnet	CMV	60 mg/kg/dose IV q8h—induction
		90-120 mg/kg/dose daily—maintenance
Cidofovir	CMV	5 mg/kg/dose IV weekly
		or
		1 mg/kg/dose IV 3×/wk—induction
		5 mg/kg q2wk—maintenance

CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

for 2 weeks or longer.[96,119,157,186,244] Resistant strains of VZV, on the other hand, are unusual.[104] Resistant HSV and VZV isolates retain virulence and can cause disease, especially extensive mucocutaneous lesions in immunocompromised hosts, but invasive diseases such as keratitis, uveitis, meningoencephalitis, and pneumonia also have occurred with resistant strains of HSV.* Immunocompromised hosts may shed resistant strains of HSV for prolonged periods and may experience recurrent disease with either sensitive or resistant strains. Such mutants are also cross-resistant to other antiviral agents that require viral TK for phosphorylation and activation (e.g., penciclovir and ganciclovir), but they are inhibited by antiviral agents that have different mechanisms of action (e.g., foscarnet, cidofovir, and trifluridine).

Pharmacokinetics

Acyclovir is available for topical, oral, and intravenous administration. Systemic absorption of acyclovir after topical application to intact skin is minimal (<0.01 μg/mL), and in one study in which acyclovir ointment was applied to zoster lesions in immunocompromised patients, plasma concentrations of less than 0.1 to 0.78 μg/mL were observed, thus suggesting some degree of percutaneous absorption.[112,542] The bioavailability of oral acyclovir is low (15% to 21%), with peak plasma concentrations of 0.4 to 0.8 μg/mL observed after the intake of one 200-mg capsule and concentrations of up to 1.6 μg/mL observed after an 800-mg dose.[54] When an equivalent dose in liquid suspension is administered to children, slightly lower peak plasma levels of 1.0 μg/mL were observed.[518] Intravenous infusion of 5 mg/kg for 1 hour provides peak plasma levels of 9.8 μg/mL, whereas plasma levels of 20.7 μg/mL are produced after a 10-mg/kg infusion.[60] Most of the administered dose of acyclovir is excreted unchanged in urine.[542] The elimination half-life of acyclovir is 2.5 to 3 hours in adult patients with normal renal function, slightly longer (3.8 hours) in neonates, and up to 20 hours in anuric patients.[54,177,248] Therefore, dose adjustment, according to creatinine clearance, is needed in patients with renal insufficiency or renal failure.[331] Probenecid administration decreases renal clearance and prolongs the half-life of acyclovir. Acyclovir is distributed widely into a variety of body fluids,

*References 96, 157, 186, 244, 280, 532.

including saliva (13% of plasma levels), vaginal secretions (15% to 170% of plasma levels), zoster vesicular fluid (90% to 100% of plasma levels), aqueous humor (37% of plasma levels), breast milk (>300% of plasma levels), amniotic fluid and placenta (>200% of plasma levels), and CSF (50% of plasma levels).[177,267,268,310,332,378] More than half the drug is removed by hemodialysis but very little after peritoneal dialysis.[320,331]

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Topical acyclovir may decrease healing time and viral shedding slightly in mucocutaneous lesions of patients experiencing primary infection with HSV.[112] Little if any clinical benefit has been documented in patients with recurrent herpes simplex lesions; however, some patients report a soothing sensation after application of ointment to the lesions. Topical therapy also may produce a mild clinical benefit in immunocompromised patients with zoster lesions.[542] Oral acyclovir significantly reduces viral shedding, clinical symptoms, and time until lesion healing in normal and immunocompromised patients with a variety of mucocutaneous lesions (e.g., orolabial, pharyngeal, genital, rectal, gingivostomatitis, whitlow, skin) associated with primary HSV infection.[12,446,557] It also has been used to treat eye disease, including dendritic corneal ulcers.[108,239]

Oral acyclovir provides benefit to normal and immunocompromised children, adolescents, and adults with primary infection with VZV (varicella or chickenpox). Treatment reduces the duration of fever by 24 hours, the mean number of skin lesions, and the time to total crusting of lesions by 2 days. Postexposure prophylaxis with oral acyclovir also may reduce the risk of acquiring varicella by close and household contacts of patients with varicella. Administration of oral acyclovir during pregnancy is likely to clinically benefit a mother with varicella, but whether it reduces the risk of congenital or neonatal disease is not clear at this time. Recurrent HSV disease also is improved with oral acyclovir therapy. When it is administered during the prodrome or at the very first sign of lesions, treatment reduces viral shedding and time to lesion healing by 1.5 to 2 days.[437,543] Long-term, continuous suppressive therapy with oral acyclovir may be of benefit in some patients with frequent episodes of recurrent mucocutaneous disease, but asymptomatic shedding and person-to-person transmission still may occur.[195,447] Patients with recurrent skin disease, whitlow, or erythema multiforme may benefit from long-term suppressive therapy with oral acyclovir. Oral acyclovir suppression also reduces recurrences of genital herpes simplex during the last trimester of pregnancy and decreases the need for cesarean section delivery.[69,468,470-472] Short-term prophylaxis administered during a period of risk for recurrence (sunlight exposure, for example) may reduce the clinical recurrence of mucocutaneous disease. Oral acyclovir reduces virus shedding, time to skin lesion healing, and the duration of zoster-associated pain.[41,102] Treatment combined with steroids also appears to decrease the frequency and severity of postherpetic neuralgia in older patients and the elderly, but specific trials conducted in children have not been performed because children seldom experience postherpetic neuralgia. Oral acyclovir also may reduce recurrence of HSV and VZV infections in bone marrow and solid-organ transplant recipients. Its effect on CMV and EBV disease in these patients, however, is minimal, if any.[519] Continuous suppressive therapy with oral acyclovir reduces cutaneous recurrences after neonatal infection when it is administered after a 14- to 21-day course of intravenous therapy has been completed.[309] Whether long-term oral suppressive therapy in neonates also prevents CNS recurrence is unclear at this time. Bell palsy associated with HSV infection may be treated with a combination of acyclovir and prednisone.[5] EBV-associated diseases have been treated with acyclovir, with variable clinical benefit.[468,479] Oral hairy leukoplakia, however, appears to respond to oral acyclovir treatment.[439,534] Treatment of patients with infectious mononucleosis reduces viral shedding but does not alter the disease course.[494] No clinical benefit has been documented when acyclovir was used to treat chronic hepatitis B.[46]

Intravenous acyclovir is used to treat all severe or life-threatening diseases caused by HSV and VZV, including encephalitis, hepatitis, neonatal disease, acute retinal necrosis syndrome, mucocutaneous disease, and zoster, with or without visceral dissemination, in both normal and immunocompromised patients.* Pediatric patients suffering from severe herpetic gingivostomatitis may benefit as well.[12] Early clinical trials also showed efficacy in the treatment of primary genital HSV infection.[111] In addition, normal patients with complications of varicella, including pneumonitis, encephalitis, and hepatitis, should receive intravenous acyclovir.[208] Other diseases associated with VZV in which acyclovir treatment is beneficial include zoster ophthalmicus with complications such as keratitis, anterior uveitis, and contralateral hemiplegia as well as acute retinal necrosis syndrome.[412,492] Intravenous acyclovir is also highly effective in reducing the incidence of disease associated with HSV and VZV in marrow and solid-organ transplant recipients. Moreover, it may help reduce serious CMV disease in selected marrow and solid-organ transplant recipients, although it clearly is not as effective as ganciclovir or other antiviral agents with specific activity against CMV.[27,28,57,379,538] Treatment of human herpes infection with simian virus B requires high doses of intravenous acyclovir administered for a prolonged period, followed by suppressive therapy.[256] Despite in vitro activity, clinical benefit has not been documented in patients with hepatitis B.[46]

As of November 2012, a shortage of intravenous acyclovir related to manufacturing delays was announced. If the shortage is still in effect, or if another shortage occurs, ganciclovir, or foscarnet secondarily, is recommended for most patients who would ordinarily have received intravenous acyclovir (www.fda.gov/Drugs/DrugSafety/DrugShortages/ucm314739.htm). Cidofovir also has

*References 60, 208, 307, 312, 322, 412, 541, 572.

activity against HSV and VZV and may also be considered in selected patients.

Dosage. Topical acyclovir as a 5 percent ointment can be applied to local lesions every 3 to 4 hours five to six times daily for 7 days.[112] If the disease is unresponsive or severe, systemic therapy with oral or intravenous acyclovir should be initiated.

Oral acyclovir is formulated as 200-mg capsules, 800-mg tablets, and a 200-mg/5 mL banana-flavored suspension. The usual dose used to treat mucocutaneous lesions caused by primary infection with HSV in adults and adolescents is 200 mg administered five times daily for 10 days. The usual pediatric oral dose is 15 mg/kg per dose (maximum, 200 mg per dose) administered five times daily for 10 days. Recurrent HSV disease in adults and adolescents may be treated with a variety of different regimens: 800 mg three times daily for 2 days, 400 mg three times daily for 5 days, or 200 mg five times daily for 5 days.[294,295,543] Suppressive doses of 400 mg administered twice daily, often for many years, seem to be safe and effective.[195] This dose, administered to pregnant women with recent primary or recurrent genital herpes, also appears to decrease recurrences at or near delivery and to diminish the need for cesarean section delivery.[69,310,512] After intravenous therapy has been completed, neonatal suppressive therapy is recommended at a dose of 300 mg/m^2 per dose administered three times daily for 6 months.[309] Because neonatal prophylaxis decreases but does not eliminate the risk for CNS recurrence and because the emergence of resistant strains has been documented, all early cutaneous lesions that recur despite compliance with oral prophylaxis, as well as other signs and symptoms suggestive of recurrent visceral or CNS disease, should be evaluated carefully in young infants, and the need for systemic therapy should be considered.[309] Oral acyclovir must be administered in higher doses to treat varicella and other VZV-associated diseases.[557] Adults and adolescents require 800-mg doses administered five times daily for 7 to 10 days or until lesions have crusted over.[32,545] The pediatric dose of acyclovir to treat varicella or chickenpox is 20 mg/kg (up to 800 mg maximum) per dose (80 mg/kg/day) administered four times daily for 5 days or until lesions have crusted.[8,147]

The usual dose for intravenous administration of acyclovir to treat serious disease associated with HSV beyond the neonatal period is 5 to 10 mg/kg per dose administered as a 1-hour infusion every 8 hours.[428,542,557] Treatment for a duration of 7 days is usually sufficient for mucocutaneous disease, but it should be continued until all lesions are healed and followed by long-term suppression if the patient remains immunocompromised. Herpes encephalitis should be treated for at least 14 days or longer, depending on clinical response and clearance of HSV DNA from the CSF.[305,307,324,556] The recommended dose to treat all forms of neonatal HSV disease (skin, eye, and mouth disease; disseminated with visceral involvement; or encephalitis) is a high-dose regimen of 20 mg/kg per dose administered every 8 hours (60 mg/kg/day).[10] Duration of intravenous treatment is at least 14 days for skin, eye, and mouth disease and at least 21 days or until HSV DNA has cleared from the CSF, whichever is longer, for encephalitis and disseminated disease.[305,307] Intravenous acyclovir treatment for neonatal HSV disease should be followed by suppression treatment with oral acyclovir at 300 mg/m^2/dose every 8 hours until at least 6 months of age to reduce risks of recurrences and to improve neurodevelopmental outcome.[10] Clinical studies have documented that these higher doses are safe in neonates but may cause renal insufficiency in older children and adults. Treatment of VZV-associated disease requires higher doses of acyclovir: 500 mg/m^2 per dose (10 to 20 mg/kg per dose) administered every 8 hours (total, 1500 mg/m^2/day) for at least 5 to 7 days or until all lesions have been crusted over for 24 to 48 hours.[542,557] In all clinical indications, the dosage of intravenously administered acyclovir should be adjusted according to creatinine clearance in patients with renal insufficiency and renal failure.

Adverse Effects. Adverse effects of acyclovir are unusual.[300] Topical application of the ointment may produce pain or local irritation, usually caused by the polyethylene glycol base.[112,542] Hand washing must be performed after each local application to lesions to avoid autoinoculation or person-to-person transmission. Oral acyclovir may cause nausea and diarrhea, rash, or headache.[542] Long-term oral administration of acyclovir appears to be safe in adults but may be associated with neutropenia in 46 percent of infants who receive suppression after treatment of neonatal HSV infection.[309,381] Intravenously administered acyclovir is generally well tolerated. However, extravasation of the drug (pH 9 to 11) can cause inflammation, ulceration, and necrosis of surrounding tissue.[300,482,522] Phlebitis also can develop. Neurotoxicity occurs rarely, usually in patients with renal insufficiency who have high serum concentrations.[40,165,209,540] Neurotoxicity associated with acyclovir is characterized by lethargy, confusion, tremor, and rarely seizures and coma. Renal tubular damage, crystalline nephropathy, or interstitial nephritis may occur in approximately 5 percent of patients.[431,461] These renal complications are more likely to develop in patients who are not adequately hydrated or in whom the drug has been infused at a rate faster than the recommended infusion time of 1 hour. Keeping urine specific gravity below 1.010 is a reasonable guideline to ensure adequate hydration. No excess frequency of adverse events has been reported to date in pregnant women who receive acyclovir or in their fetuses or newborns.* Therefore, on the basis of available information, acyclovir seems to be safe when it is administered during pregnancy, especially during the last trimester, and does not appear to have any significant adverse effects.

Valacyclovir

Spectrum of Activity

Valacyclovir (L-valine, 2-[(2-amino-1,6-dihydro-6-oxo-9*H*-purin-9-yl)methoxy]ethyl ester monohydrochloride,

*References 69, 83, 310, 468, 472, 572.

also known as valacyclovir hydrochloride) is the hydrochloride salt of the L-valine ester of acyclovir.[42] It has essentially the same selective spectrum of antiviral activity against the herpesviruses as acyclovir does.[48]

Mechanism of Action and Resistance

Valacyclovir is converted rapidly to acyclovir and therefore has the same mechanisms of action and resistance as acyclovir does.[48] Viral isolates that are resistant to acyclovir will be resistant to valacyclovir.

Pharmacokinetics

The pharmacokinetics of valacyclovir have not been studied in the pediatric population, but information gained from adults can be applied, in many ways, to pediatric patients. After oral administration, valacyclovir is absorbed rapidly from the gastrointestinal tract. It is metabolized by first pass through the intestinal tract and also by the liver into acyclovir and L-valine.[48] It has the advantage over acyclovir of having 54 percent bioavailability (versus 20% for acyclovir), which is not altered by food.[498] A single dose of 1 g of valacyclovir administered to an adult produces plasma levels of 0.4 to 0.8 μg/mL. The half-life is 2.5 to 3 hours, similar to that of acyclovir, and is prolonged in patients with renal insufficiency or renal failure.[547,551] The drug is removed by hemodialysis. The rate but not the extent of conversion of valacyclovir to acyclovir is prolonged in patients with liver disease.

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Valacyclovir has been reported to be effective in treatment of primary and recurrent mucocutaneous disease caused by HSV-1, HSV-2, and VZV.* Randomized clinical trials conducted in adult patients showed valacyclovir to be superior to placebo and comparable to acyclovir in reducing the number and duration of lesions, pain, and time to healing in patients with primary and recurrent genital herpes and zoster.[56,438,565] It is also comparable to acyclovir for suppression of genital herpes recurrences. Furthermore, in a study of 27 CMV-seropositive heart transplant recipients, valacyclovir appeared to be equal or superior to oral acyclovir in preventing both laboratory and clinical parameters of CMV reactivation.[149] Because valacyclovir is converted to acyclovir, it is likely to be effective for all the clinical indications for which acyclovir has been shown to be effective.

Dosage. Valacyclovir is available only in 500-mg caplets; therefore, a pediatric liquid formulation is not available at this time. The usual dose is 1 g twice daily for 10 days for primary genital herpes and 500 mg twice daily for 3 to 5 days for recurrent disease.[48,56,337,465] A daily dose of 500 mg has been used safely for longer than a year to suppress recurrences of HSV disease.[357] The dose to treat VZV-associated disease is higher than that for HSV-associated disease. A dose of 1 g three times a day for at least 7 days is usually necessary to treat zoster, and therapy should be continued until the lesions have dried.[49] The dose of valacyclovir should be adjusted according to creatinine clearance in patients with renal insufficiency or renal failure.

Adverse Effects. The adverse effects of oral valacyclovir are similar to those of oral acyclovir and include gastrointestinal disturbances such as nausea, vomiting, and diarrhea.[48] Headache and behavioral changes also have been observed. Overdosage may produce precipitation of acyclovir in the renal tubules as well as CNS toxicity.

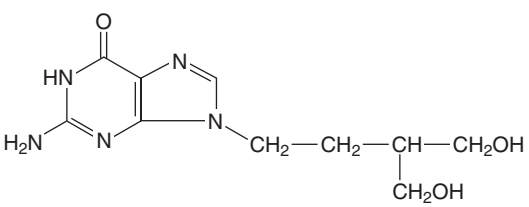
Penciclovir

Spectrum of Activity

Penciclovir (9-[4-hydroxy-3-hydroxymethylbut-1-yl] guanine) is an acyclic guanosine analogue with a selective spectrum of activity against the herpesviruses similar to that of acyclovir[63] (Fig. 238-7). This compound inhibits HSV-1 at very low concentrations (0.2 to 0.6 μg/mL) and HSV-2 at slightly higher concentrations (0.3 to 2.4 μg/mL).[25,63,196,550] At even higher concentrations (0.9 to 4.0 μg/mL), it inhibits VZV.[25,26] The compound has very little activity against CMV, and concentrations greater than 50 μg/mL are required to inhibit CMV. However, penciclovir does have activity against HBV.[107,318,475]

Mechanism of Action and Resistance

Like acyclovir, penciclovir is preferentially phosphorylated by viral TK in virus-infected cells to penciclovir monophosphate and by cellular enzymes to penciclovir triphosphate, which is the active form of the drug.[148] Penciclovir triphosphate competitively inhibits viral DNA polymerase. It is approximately 100 times less potent than acyclovir triphosphate in inhibiting viral DNA polymerase, but an antiviral effect is achieved because it is present in high concentrations for a prolonged period (7 to 20 hours) in virus-infected cells. However, unlike acyclovir, penciclovir is not a chain terminator during DNA synthesis. Penciclovir triphosphate also inhibits the DNA polymerase of HBV. Emergence of HSV strains resistant to penciclovir has been minimal.[335] Similar to HSV isolates resistant to acyclovir, isolates resistant to penciclovir may have viral TK gene mutations that produce mutants with deficient or altered TK activity, or they may have mutations in DNA polymerase



Penciclovir

FIGURE 238-7 ■ Structure of penciclovir.

*References 48, 49, 56, 337, 438, 465.

genes.[91] Strains of acyclovir-resistant HSV that are TK-deficient mutants also will be resistant to penciclovir, but strains of acyclovir-resistant HSV that are TK altered may be susceptible to penciclovir.[64,418]

Pharmacokinetics

Penciclovir is poorly absorbed after oral administration.[173] Adults who received a 10-mg/kg intravenous infusion of penciclovir had plasma levels of 12 μg/mL, but no pediatric information is available. Penciclovir 1 percent cream is not absorbed systemically. The systemic pharmacokinetics of penciclovir are discussed under famciclovir.

Clinical Indications, Dosage, and Adverse Effects

Penciclovir is available in the United States as a 1 percent cream in a propylene glycol base and is licensed for the treatment of herpes labialis lesions on the lips and face. Maximal clinical benefit occurs when the cream is applied to the lesions early, at the first clinical sign of disease, every 2 hours while awake for 3 to 5 days.[464] Application of penciclovir cream may be associated with local skin reactions, most likely caused by the propylene glycol base. An intravenous form of penciclovir has been tested in Europe, but it is not available in the United States. Penciclovir is not absorbed orally, but it is available as the oral prodrug famciclovir, which is converted rapidly to penciclovir. Dosages and systemic adverse effects of penciclovir are discussed under famciclovir.

Famciclovir

Spectrum of Activity

Famciclovir, 2-[(2-amino-9*H*-purin-9-yl)]-1,3-propanedial diacetate, is the prodrug of the antiviral agent penciclovir, which has selective activity against HSV-1, HSV-2, VZV, and HBV.

Mechanism of Action and Resistance

Famciclovir undergoes rapid transformation to penciclovir, which is monophosphorylated by viral TK to penciclovir monophosphate; the monophosphate, in turn, is converted by cellular enzymes to penciclovir triphosphate, the active form of the antiviral compound. Penciclovir then competitively inhibits viral DNA polymerase and, thereby, viral replication. The prolonged intracellular half-life observed with penciclovir also is observed with famciclovir. Penciclovir-resistant strains of HSV and VZV occur when mutations produce deficient or altered TK or altered DNA polymerase. Most TK-deficient acyclovir-resistant strains of HSV are also resistant to penciclovir.

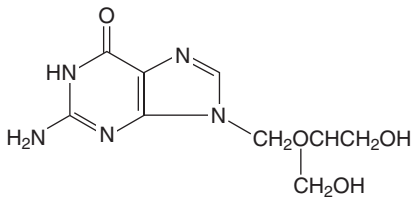
Pharmacokinetics

Famciclovir is the diacetyl-6-deoxy analogue of the antiviral compound penciclovir. After oral administration, famciclovir is absorbed rapidly from the gastrointestinal tract with excellent (77%) bioavailability, and then it is metabolized in the liver by deacetylation and oxidation to form penciclovir. Single oral doses of 250 and 500 mg of famciclovir administered to adults produce peak plasma penciclovir levels of 1.6 to 1.9 μg/mL and 2.7 to 4.0 μg/mL, respectively. Administration of famciclovir with food reduces peak plasma concentrations by slowing the absorption time but does not alter the overall bioavailability of the drug. The half-life for penciclovir is 2 to 3 hours, after which it is excreted by filtration and active tubular secretion by the kidneys. Nonrenal clearance by fecal excretion also occurs for as much as one third of the oral dose. Excretion of penciclovir is decreased in patients with renal insufficiency and renal failure, and in patients with liver disease, peak plasma levels may be reduced.[58] Penciclovir is removed from the body by hemodialysis. After oral administration of famciclovir to rats, penciclovir is concentrated in breast milk; however, no studies have been performed in lactating mothers to confirm such concentration in humans.

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. In adult clinical trials, oral famciclovir was as effective as oral acyclovir and superior to placebo in treatment of recurrent mucocutaneous infections with HSV and VZV in both normal and immunocompromised patients.[99,358,452,535] When famciclovir was given early in the course of illness, time to lesion crusting and healing, duration of viral shedding, and length of acute pain all were shortened. In some studies, the duration of postherpetic neuralgia in elderly patients with zoster also was shortened.[535] Although to date it has not been studied specifically in clinical trials of patients with primary HSV and VZV infection, famciclovir probably also will provide clinical benefit in these conditions.[348] In addition, famciclovir is effective as suppressive therapy to reduce HSV recurrences and viral shedding.[133,377] Famciclovir also has been used to treat chronic HBV infection and for prophylaxis against recurrent HBV infection in liver transplant recipients.[214,358] No clinical trials in pediatric patients have been conducted.

Dosage. Famciclovir is available in 125-, 250-, and 500-mg tablets. An oral suspension for pediatric use is not available. The usual recommended oral dose of famciclovir to treat primary and recurrent mucocutaneous HSV disease is 125 mg twice daily for 5 days.[452] Dosages of suppressive therapy are slightly higher, 250 mg twice daily for as long as 1 year. Of note, clinical trials showed that single daily doses of 250 mg were not as effective as the twice-daily regimen in suppressing recurrences. For immunocompromised patients, especially those infected with HIV, even higher doses (500 mg twice daily for 7 days) may be necessary.[462] Treatment of VZV-associated disease, such as zoster, also requires higher doses (500 mg twice or three times daily for 10 days).[535] All dosage regimens should be reduced, according to creatinine clearance, in patients with renal insufficiency or renal failure.



Ganciclovir

FIGURE 238-8 ■ Structure of ganciclovir.

Adverse Effects. Adverse effects of treatment with oral famciclovir are unusual and include gastrointestinal disturbances, such as nausea and diarrhea; rash; CNS complaints, such as confusion, hallucinations, and disorientation; neutropenia; and elevated liver transaminases.[99,122,457]

Ganciclovir

Spectrum of Activity

Ganciclovir, 9-(1,3-dihydroxy-2-propoxymethyl)guanine (also known as DHPG), is an analogue of deoxyguanosine, similar to acyclovir, yet different in that it has an additional hydroxymethyl group on the acyclic side chain[164,167,425,484] (Fig. 238-8). This antiviral compound has selective activity against the herpesviruses, with uniquely potent antiviral activity against CMV. Ganciclovir inhibits HSV-1 and HSV-2 at 0.05 to 0.6 μg/mL, VZV at 0.4 to 10 μg/mL, CMV at 0.02 to 3.4 μg/mL, and EBV at 1.5 μg/mL. Human herpesvirus types 6 (HHV-6), 7 (HHV-7), and 8 (HHV-8) also may be inhibited by ganciclovir.[299] It has in vitro activity against adenoviruses and HBV as well.[164,192,390,488] High concentrations (30 to >700 μg/mL) of ganciclovir will inhibit the growth of most uninfected mammalian cells; bone marrow–derived cells, however, appear to be uniquely sensitive and can be inhibited at much lower concentrations (<0.7 μg/mL).

Mechanism of Action and Resistance

Ganciclovir is monophosphorylated in infected cells by virus-induced enzymes: TK in HSV-infected cells and protein kinases that are encoded by the UL97 phosphotransferase gene in CMV-infected cells.[51,164,343,484] Cellular enzymes complete the phosphorylation to ganciclovir triphosphate, the active form of the compound, which is concentrated in infected cells. Ganciclovir triphosphate competitively inhibits the incorporation of deoxyguanosine triphosphate into viral DNA, where it slows and stops viral DNA chain elongation and produces short, noninfectious viral DNA fragments.[216] Ganciclovir also preferentially inhibits viral DNA polymerase.[351] Ganciclovir resistance has been detected in 8 to 38 percent of immunocompromised adult and pediatric patients who have received prolonged administration of ganciclovir, and such resistance is an important clinical problem.[93,142,191,466,495,531]

Patients may be infected with single or multiple strains of CMV, with both drug-sensitive and drug-resistant strains mixed in the population or in different body compartments.[159] Resistant strains may be induced or infect a patient primarily, emerge quickly after only weeks of therapy, or evolve more slowly and emerge sequentially after several months of antiviral prophylaxis or therapy.[94,159,277,448,557,566] These resistant mutants also retain virulence and are capable of producing serious and progressive disease.[59,159,277,455,491] Ganciclovir resistance in CMV strains occurs by at least two mechanisms: (1) point mutations or deletions in the UL97 gene that reduce intracellular phosphorylation of ganciclovir and (2) point mutations in the viral DNA polymerase UL54 (pol) gene that alter the function of the polymerase.[93,351,489,506] Most strains of CMV that are resistant to ganciclovir have UL97 mutations (most commonly at codons 460, 520, 594, and 595) and reduced phosphorylation, but they remain susceptible to foscarnet and cidofovir.[92,93,506] However, CMV strains that are resistant to ganciclovir because of a mutation in the UL54 DNA polymerase gene also may be resistant to foscarnet or cidofovir or to both.[351,458] Moreover, multiple highly resistant strains of CMV may occur if both UL97 phosphotransferase and UL54 DNA polymerase gene mutations are present.[94,489] Resistance conferred by UL54 mutations usually emerges after UL97 mutations have occurred.[191,489] Ganciclovir resistance in HSV occurs in TK-deficient, acyclovir-resistant strains of the virus.

Pharmacokinetics

Intravenous administration of a 5-mg/kg dose of ganciclovir in adults produces peak plasma levels of 8 to 11 μg/mL.[164,170] Similar pharmacokinetics in 10 pediatric patients aged 9 months to 12 years has been observed.[182] A study of the pharmacokinetics of ganciclovir in 27 neonates aged 2 to 49 days who were administered intravenous ganciclovir for treatment of congenital CMV disease showed a dose of 6 mg/kg to be the most appropriate dose for that age group, down to 32 weeks of gestation.[532,578] After intravenous administration, ganciclovir is distributed in CSF at 24 to 70 percent of plasma levels, and 38 percent of plasma levels enter brain tissue.[97,99] Drug levels in aqueous, vitreous, and subretinal fluid in the eye are comparable to serum levels, and even higher levels can be achieved with intravitreal implants.[19,170,321,360,391] Ganciclovir also accumulates in breast milk in animal models.[6] The plasma half-life is 2 to 4 hours in adults with normal renal function and longer than 24 hours in patients with renal insufficiency and renal failure.[494] The drug is eliminated by renal excretion, and dose reduction is required for patients with impaired creatinine clearance. Hydration will enhance elimination of the drug, and hemodialysis removes 60 percent of ganciclovir in plasma.[494] Ganciclovir also can be administered orally.[500] Its oral bioavailability is rather poor: 5 percent under fasting conditions and 6 to 9 percent if it is administered with food.[15,333] Oral doses of 1000 mg administered to adults every 8 hours produce plasma levels of 0.9 to 1.2 μg/mL.[15,460] The valine ester prodrug of ganciclovir, valganciclovir, has high oral bioavailability

and efficacy equal to that of intravenous ganciclovir for prevention and treatment of mild to moderate CMV disease in transplant recipients and treatment of congenitally infected newborns.[150,290,359]

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Ganciclovir is used for the treatment of established CMV disease; for early or preemptive therapy in immunocompromised patients with virologic markers of active infection that are predictive of CMV disease; and for prophylaxis of high-risk patients, such as those who are CMV seropositive or who have received transplants from CMV-seropositive donors.[76] Ganciclovir is licensed for treatment and chronic suppression of sight-threatening CMV retinitis in immunocompromised patients and for prevention of CMV disease in transplant recipients. Clinical trials have demonstrated efficacy in these conditions.* Treatment with ganciclovir also is beneficial in immunocompromised individuals with other forms of invasive CMV disease, including pneumonia, colitis, esophagitis, myocarditis, encephalitis, persistent fever and leukopenia syndrome, and viral sepsis syndrome.† Treatment of established CMV pneumonia in bone marrow and stem cell transplant recipients is difficult, and the disease may not respond to ganciclovir treatment, with or without immune modulators or globulins.[153] Most clinical trials have been performed in adults, but children and infants with CMV disease benefit from treatment as well. Ganciclovir treatment also has been evaluated in newborns congenitally infected with CMV with CNS involvement.[307,492,578] In addition, ganciclovir is used for preemptive therapy for patients (primarily recipients of solid-organ, marrow, and stem cell transplants) with virologic markers that are predictive of serious CMV disease.[68,198,241,502] Prophylaxis with ganciclovir to prevent CMV infection and disease in immunocompromised patients, including solid-organ and bone marrow transplant recipients and patients with acquired immunodeficiency syndrome (AIDS), also has been beneficial in most groups studied.‡ Prophylaxis reduces the risk for the acquisition of serious CMV disease or, in some groups, prolongs the incubation period, but it does not eliminate the risk.[146,197,506,563] Ganciclovir prophylaxis is also effective in preventing HSV infection in immunocompromised patients.[197] Ganciclovir appears to decrease HBV DNA levels and to improve hepatic enzymes in patients with posttransplantation infection or reactivation with HBV.[192] In addition, ganciclovir has been used to treat patients with serious disease associated with adenovirus infection, but clinical trials proving efficacy have not been performed.[528]

Dosage. Ganciclovir is supplied as a solution for intravenous infusion and as 250- and 500-mg capsules for oral administration. The intravenous infusions are delivered best in a concentration of 10 mg/mL or less and administered during a 1-hour period. Intravitreal implants are also available and are designed to slowly release relatively large doses of ganciclovir locally into the eye during a period of many months. Ganciclovir therapy for serious CMV disease usually is administered in two phases, induction and maintenance. The recommended dose for induction therapy for serious CMV disease in adults and children with normal renal function is 5 mg/kg per dose administered intravenously every 12 hours for 2 to 3 weeks. Successful induction therapy is accompanied by clinical and virologic response. Maintenance therapy at doses of 5 mg/kg/dose administered intravenously every 12 to 24 hours should be continued in severely immunocompromised patients who are at risk for relapse. Selected patients may receive oral ganciclovir for maintenance therapy. The usual recommended dose for adults is 1000 mg three times daily or, alternatively, 500 mg administered six times daily. The pediatric dose for maintenance oral therapy has not been established. The duration of maintenance therapy should be individualized for each patient, but such therapy usually lasts through the period of greatest risk, such as rejection or immune suppression, or may be lifelong, as in patients with AIDS. Some patients who experience CMV disease, such as solid-organ transplant recipients with minimal immune suppression and minimal or no rejection, will respond dramatically to induction therapy and will not require long-term maintenance therapy. A dose of 6 mg/kg administered every 12 hours for 6 weeks has been used to treat newborns with congenital CMV disease.[307,308,329,578] This dose appears to be adequate for term newborns and premature newborns as young as 32 weeks' gestation, provided renal function seems to be normal for age. The dose for extremely premature newborns is not known and should be individualized according to the clinical judgment of the infectious diseases specialist. Preemptive therapy, 5 mg/kg per dose administered every 12 hours, is initiated when virologic markers for active, invasive infection, such as positive cultures for CMV from bronchoalveolar lavage samples or the presence of CMV DNAemia or antigenemia, are identified by routine virologic surveillance.[301,506] After an induction period of 7 to 14 days, maintenance therapy usually is continued for 100 to 120 days after transplantation or longer if the patient remains at high risk for relapse of CMV disease. Prophylaxis with ganciclovir is administered immediately before transplantation and for a defined period after transplantation in patients who are at high risk, such as those who are CMV seropositive before transplantation and those who receive marrow or solid-organ transplants from a CMV-seropositive donor.*

Patients who do not respond to induction therapy or who relapse or progress during maintenance therapy with ganciclovir may have a resistant strain of CMV. The addition of another antiviral with different mechanisms of action, such as foscarnet or cidofovir, may be beneficial. If clinical or virologic responses still are not maintained, the possibility of a multiply resistant CMV strain should be considered. Patients with disseminated adenovirus

disease have received doses of 5 mg/kg every 12 hours for 14 or more days, but clinical benefit has not been proved.[390]

Adverse Effects. Adverse effects of ganciclovir can be both local and systemic. Local reactions, such as phlebitis, irritation, blistering, and ulceration at or around the infusion site, can occur and usually are attributed to the alkaline pH (pH 11) of the intravenous solution. Local reactions can be minimized by paying careful attention to the infusion site or by administering the antiviral agent through a central venous catheter. The most common systemic toxicity associated with ganciclovir administration is dose-dependent, reversible neutropenia, which occurs in a third to a half of patients (adults, children, and newborns) who receive this antiviral for longer than 2 weeks.[118,164] Thrombocytopenia also can occur, most often in patients with AIDS who are receiving other antiviral agents, including antiretrovirals.[252] If the neutropenia is severe (absolute neutrophil count <500/mm^3), ganciclovir administration should be halted temporarily until the neutrophil count recovers. Ganciclovir then may be readministered, if it is still clinically indicated, at the same or half the original dose while the patient is carefully monitored for recurrence of the neutropenia. Some experts have used recombinant granulocyte-macrophage colony-stimulating factor successfully to treat ganciclovir-induced neutropenia.[218] Anemia associated with ganciclovir administration is an unusual occurrence. Other adverse effects associated with ganciclovir include CNS disturbances, such as headache, behavioral changes, psychosis, seizures, and coma; mild nephrotoxicity with azotemia; liver dysfunction with elevated transaminases; and rash. Ganciclovir also is mutagenic, carcinogenic, and immunosuppressive. In addition, preclinical animal studies showed reproductive toxicity, with teratogenicity, embryotoxicity, and testicular atrophy.[164] Long-term studies in children who received ganciclovir as newborns are being conducted to determine the long-term effects of ganciclovir administration, if any. Also, caretakers who prepare and administer ganciclovir to patients should take precautions to minimize direct exposure to the antiviral agent.

Valganciclovir

Spectrum of Activity

Valganciclovir (L-valine, 2-[(2-amino-1,6-dihydro-6-oxy-9*H*-purin-9-yl)methoxy]-3-hydroxypropyl ester) is a prodrug of ganciclovir and therefore has the same selective spectrum of activity as ganciclovir against herpesviruses, especially CMV, as well as limited activity against adenoviruses and HBV.

Mechanism of Action and Resistance

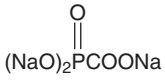
Valganciclovir is the L-valyl ester (prodrug) of ganciclovir.[359] It is metabolized rapidly in the body to ganciclovir. Ganciclovir then is monophosphorylated by viral protein kinase (coded for by UL97 genes) in CMV-infected cells and further phosphorylated to the active form ganciclovir triphosphate by cellular kinases. Viral DNA synthesis is inhibited by ganciclovir triphosphate (see ganciclovir for details). Isolates of CMV become resistant to valganciclovir by mutations in UL97, the viral kinase gene, or in UL54, the viral DNA polymerase gene. Mutations in UL97 confer resistance to ganciclovir and therefore to valganciclovir, whereas mutations in UL54 confer double or triple resistance to ganciclovir, foscarnet, and cidofovir. Mutations in both genes can produce highly resistant strains of CMV.

Pharmacokinetics

Valganciclovir is well absorbed after oral administration and is rapidly hydrolyzed in the intestine and liver to ganciclovir.[419] The bioavailability of valganciclovir is high, approximately 60 percent (vs. 6% to 9% for ganciclovir), and an oral dose of 900 mg administered to adults produces ganciclovir blood levels equivalent to a 5-mg/kg dose administered intravenously.[70,289,359] Absorption is enhanced significantly with the ingestion of food, so physicians recommend that valganciclovir be taken with food or meals. The drug is excreted by the kidneys, and renal insufficiency produces prolonged excretion and a longer half-life (see ganciclovir). Oral valganciclovir solution has been administered to neonates and infants up to 6 months of age, at a dosage of 16 mg/kg/dose (range of 15 to 18 mg/kg/dose) every 12 hours. Valganciclovir is 41% bioavailable and provides stable and constant plasma concentrations and antiviral effects comparable to intravenously administered ganciclovir.[310,472] Pharmacokinetic studies have shown stable and effective antiviral plasma concentrations (mean trough, 0.51 μg/mL; and mean 2-hour peak, 3.81 μg/mL).[345]

Clinical Indications, Dosage, and Adverse Effects

Valganciclovir is available in 450-mg tablets, and the usual adult dose is 900 mg (two 450-mg tablets) twice daily for 14 days (induction therapy), followed by a maintenance dose of 900 mg administered once daily.[359] An oral solution (50 mg/mL concentration) is also licensed and available.[306] Valganciclovir is licensed for induction and maintenance treatment of CMV retinitis in immunocompromised patients, but clinical trials have shown that valganciclovir is beneficial to a variety of patients with a number of different CMV infections.[359] Antiviral prophylaxis or preemptive treatment for CMV DNAemia with valganciclovir for 100 to 200 days after transplantation in high-risk transplant recipients significantly reduces the incidence of CMV disease and improves graft survival.[565] Treatment of newborns with symptomatic congenital CMV infection with oral valganciclovir (15-18 mg/kg/dose every 12 hours) appears beneficial, similar to intravenous ganciclovir benefits, providing improved head circumference, improved developmental milestones, and reduced risk of hearing loss and progression. A randomized clinical trial comparing 6 weeks versus 6 months of treatment in congenitally infected newborns has recently shown the longer 6-month duration of treatment to be more beneficial.[11] In some centers,



Foscarnet

FIGURE 238-9 ■ Structure of foscarnet.

treatment up to 12 months of age has shown benefit for prevention of hearing loss progression.[13] There are case reports of the use of valganciclovir or ganciclovir to treat newborns with asymptomatic congenital CMV with hearing loss, but conclusions about the efficacy of such treatment cannot be made from these reports at this time.[323,570]

As with ganciclovir, if a patient treated with valganciclovir experiences progression of disease or recurrence during maintenance therapy, a resistant strain of CMV should be considered a possibility and antiviral treatment adjusted accordingly. Adverse effects associated with the oral administration of valganciclovir include diarrhea and dose-dependent, reversible neutropenia.[359]

Foscarnet

Spectrum of Activity

Foscarnet (phosphonoformic acid or trisodium phosphonoformate hexahydrate) is a pyrophosphate analogue that selectively inhibits herpesviruses[405] (Fig. 238-9). It also has activity against HIV and HBV.[29,161] At concentrations of 100 to 300 µmol/L, CMV is inhibited; whereas slightly lower concentrations (80 to 200 µmol/L) inhibit HSV types 1 and 2, VZV, EBV, and HHV-8.[405] Concentrations between 20 and 200 µmol/L appear to inhibit HBV. Foscarnet also inhibits most but not all acyclovir-resistant HSV and VZV strains and most but not all ganciclovir-resistant CMV strains.[176,354,453] Combinations of ganciclovir and foscarnet are synergistic against CMV, and combinations of zidovudine and foscarnet appear to be synergistic against HIV.[161,354] At high concentrations (500 to 1000 µmol/L), foscarnet inhibits cellular DNA synthesis in uninfected cells.[95]

Mechanism of Action and Resistance

Foscarnet is not a nucleoside analogue, and it does not require phosphorylation or any other form of intracellular metabolism to be activated. Rather, it is a pyrophosphate analogue that directly inhibits viral and cellular DNA polymerase.[117,132] Selective viral inhibition is accomplished by noncompetitive and reversible blocking of the pyrophosphate binding site of the viral polymerase, in much lower concentrations than it inhibits cellular DNA polymerases. Because foscarnet does not require phosphorylation by viral TK or other kinases, it inhibits TK-deficient and altered strains of HSV and VZV that are resistant to acyclovir as well as UL97 phosphotransferase mutants of CMV that are resistant to ganciclovir. However, strains of herpesviruses of all types that are resistant to acyclovir or ganciclovir by mutation of the viral DNA polymerase gene are also resistant to foscarnet.[30,455]

Pharmacokinetics

Intravenous administration of 60 mg of foscarnet every 8 hours to adults produces plasma levels of 450 to 575 µmol/L; 90 mg administered every 12 hours produces plasma levels of 420 to 746 µmol/L.[132,453] CSF levels are usually approximately 60 percent of plasma levels, and vitreous concentrations in the eye are the same as or slightly higher than plasma levels.[237] Most (80%) of the dose of foscarnet is eliminated unmetabolized from the body through the kidneys, and plasma clearance decreases if renal function is impaired. The remaining 20 percent appears to be deposited in teeth and bone, where it accumulates and remains for months. The drug is removed by hemodialysis, but not appreciably by peritoneal dialysis.[7,352] Oral foscarnet has poor bioavailability (less than 10%) and causes diarrhea, and it is unlikely to be available for patient use.[404] Pharmacokinetic data in infants and children have not been published. However, preclinical studies showed that deposition of foscarnet in teeth and bones is greater in younger than in older animals.

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Foscarnet is licensed for both induction and maintenance treatment of CMV retinitis in immunocompromised patients and for treatment of mucocutaneous disease caused by acyclovir-resistant HSV.* Foscarnet also may be of benefit in patients with varicella or zoster caused by acyclovir-resistant VZV.[453] Because the combination of foscarnet and ganciclovir appears to be synergistic in vitro, immunocompromised patients who experience progression or relapse of CMV disease while receiving therapy with one or the other antiviral agent may benefit from combination therapy in some instances.[24,143,176,281] Foscarnet also may be used for the treatment or prophylaxis of serious or life-threatening CMV disease when ganciclovir is contraindicated or otherwise deemed clinically undesirable because of its myelosuppressive effects.[24,440,571] The antiretroviral properties of foscarnet, when it is combined with other antiviral agents, also may be beneficial in patients with HIV infection or AIDS.[45,283,411,513,514]

Dosage. Treatment with foscarnet usually is divided into two phases, induction and maintenance. The usual dosage of foscarnet for induction therapy is 60 mg/kg per dose administered intravenously every 8 hours for 3 weeks; maintenance therapy is 90 to 120 mg/kg/day administered indefinitely or through the period of risk.[293] The dose of foscarnet should be given slowly, during the course of 2 hours (or no faster than 1 mg/kg/min), to reduce renal toxicity. Creatinine clearance should be used to adjust dosage regimens in patients with renal insufficiency or renal failure. Published experience on the use of foscarnet in pediatric patients is limited, but undoubtedly, certain pediatric patients benefit from receiving

*References 132, 143, 281, 334, 352, 411, 455, 473, 474, 546.

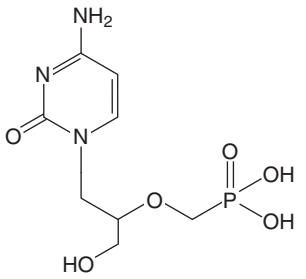
foscarnet therapy.[546] In these cases, the same per-kilogram dosage regimens can be used for most patients. Prehydration with saline and the use of probenecid with each dose are recommended in some patients to reduce renal toxicity.

Adverse Effects. Foscarnet is associated with serious adverse effects and should be used only after thorough consideration of the risks and benefits involved.[95,132] Renal toxicity with azotemia, proteinuria, crystalluria, renal tubular acidosis or necrosis, and interstitial nephritis can occur in as many as a third of patients who receive foscarnet.[130,287] Renal toxicity generally occurs after the first week of therapy and usually is reversible. The risk for the development of renal toxicity is increased if the drug is given by rapid infusion or administered in high doses, if the patient is dehydrated, or if other nephrotoxic drugs are administered concomitantly with foscarnet.[396] Hydration, including saline loading, and administration of each dose during the course of at least 2 hours appear to reduce the risk for development of renal toxicity. Foscarnet binds divalent metal ions such as calcium in the body, and metabolic abnormalities, including hypocalcemia and hypercalcemia (total or ionized), hypophosphatemia and hyperphosphatemia, hypomagnesemia, and hypokalemia, may occur in approximately a third of patients who receive foscarnet.[282] Symptoms of these acute metabolic abnormalities include perioral tingling, numbness or paresthesias of the limbs, and, if severe, seizures, tetany, and cardiac dysrhythmias. Administration of the dose during the course of at least 2 hours also reduces the risk for development of metabolic abnormalities. Foscarnet also can be deposited and concentrate in bone, with as yet unclear long-term consequences.[132] CNS side effects also occur in approximately a fourth of patients and include headache, tremor, seizures, and behavioral changes. Abnormal liver function test results have been noted, and high urinary concentrations of foscarnet may produce painful genital ulcerations and rash in some patients.[242,492] Preclinical studies showed foscarnet to be mutagenic and associated with anomalies of skeletal development in young animals.[129]

Cidofovir

Spectrum of Activity

Cidofovir, (*S*)-1-3-hydroxy-2-[phosphonomethoxypropyl]) cytosine dihydrate (also known as HPMPC), is an acyclic phosphonate nucleotide analogue of deoxycytidine monophosphate with broad-spectrum in vitro antiviral activity against all DNA viruses, including herpesviruses (HSV types 1 and 2; CMV, EBV, and VZV; and HHV types 6, 7, and 8), adenoviruses, polyomaviruses (JC and BK viruses), papillomaviruses, and poxviruses (vaccinia, variola or smallpox, cowpox, monkeypox, camelpox, and molluscum contagiosum and orf viruses) (Fig. 238-10).* Cidofovir exhibits its most specific and potent antiviral activity against CMV (minimal inhibitory concentration, 0.25 μmol/L).[88,89,141,154] The compound also is very active against VZV (0.79 μmol/L), HSV-1 (12.7 μmol/L), and acyclovir-resistant, TK-deficient HSV-1 strains (6.24 μmol/L).[250,374,493] Cidofovir inhibits HSV-2 at concentrations of 31.7 μmol/L, adenoviruses at 10.8 μmol/L, and vaccinia virus at 12.7 μmol/L.[128,199,486] Strains of CMV UL97 mutants that are resistant to ganciclovir are inhibited by cidofovir, and cidofovir in combination with ganciclovir or foscarnet shows synergistic inhibition of CMV in vitro.[454]



Cidofovir

FIGURE 238-10 ■ Structure of cidofovir.

Mechanisms of Action and Resistance

Cidofovir inhibits the replication of CMV and other viruses by selective inhibition of viral DNA polymerase.[89,250,374] The compound is phosphorylated by cellular enzymes to the active form cidofovir diphosphate. Cidofovir diphosphate inhibits both viral and cellular DNA polymerase; however, because the concentration necessary to inhibit cellular DNA synthesis is hundreds of times higher than that needed to inhibit viral DNA synthesis, cidofovir appears to selectively inhibit viral DNA synthesis at concentrations safely administered to humans. Cidofovir diphosphate has a long intracellular half-life that provides prolonged and persistent antiviral activity and allows infrequent dosing regimens in humans.[171,251,493] Because the compound does not require TK for initial phosphorylation, it is active against TK-deficient and TK-altered acyclovir-resistant HSV strains.[374] Resistance to cidofovir is unusual but can occur by mutations in viral DNA polymerase genes (codons 375 to 540 and possibly 978 to 988), most likely in patients who have received prolonged or repeated periods of treatment with ganciclovir or foscarnet. Strains of CMV that are resistant to cidofovir are also usually resistant to ganciclovir, and occasionally, triple mutants resistant to ganciclovir, foscarnet, and cidofovir occur.[141,527]

Pharmacokinetics

After an intravenous infusion of 5 mg/kg of cidofovir, peak plasma levels range from 11.6 to 26.1 μg/mL, with the latter occurring after administration of probenicid.[121,454,527] The plasma half-life is 2 to 3 hours, but the intracellular half-life is prolonged (between 17 and 65

*References 16, 88, 89, 128, 141, 154, 188, 199, 250, 374, 396, 397, 454, 482, 483, 486, 493, 536.

hours).[493] CSF penetration by cidofovir is not well studied, but in at least one patient, the drug did not appear to cross the blood-brain barrier in detectable amounts. After topical administration to the eye or intact skin, systemic absorption is low, with peak plasma levels usually less than 0.5 μg/mL.[326,327] However, patients with abraded or denuded skin may have significant absorption.[49] The systemic absorption that occurs after intralesional or subcutaneous administration is not well characterized at this time. Intravitreal administration produces sustained antiviral effects in animal models.[171] Cidofovir is not well absorbed orally, with less than 5 percent bioavailability. However, bioavailable alkoxyalkyl esters of cidofovir are in development and may lead to an oral compound in the near future.[301] Aerosolized cidofovir also is being studied in animal models and appears to deliver high concentrations of antiviral to the lungs.[67] Cidofovir is eliminated through the kidney by glomerular filtration and active tubular secretion, and more than 90 percent of the original dose can be recovered unchanged in urine.

Clinical Indications, Dosage, and Adverse Effects

Clinical Indications. Cidofovir is licensed for induction and maintenance treatment of CMV retinitis in immunocompromised adults with AIDS.[454,515] Clinical trials have shown that cidofovir significantly delays progression of CMV retinitis in previously untreated patients as well as in those who previously failed to respond to or were intolerant of foscarnet or ganciclovir therapy.* Cidofovir also has been shown to be effective for the treatment of CMV infection and disease in marrow and stem cell transplant recipients. In addition, it has been used, in selected patients, for preemptive treatment of CMV infection after marrow and stem cell transplantation.[85,344,424] One study also showed that cidofovir helped prevent posttransplantation CMV-associated atherosclerosis in rats.[73] Patients infected with CMV strains resistant to ganciclovir or foscarnet, or both, may benefit from receiving cidofovir treatment.[141] Cidofovir is used by clinicians to treat immunocompromised children with serious CMV disease despite the lack of published experience in children.[75,82]

Cidofovir has broad-spectrum antiviral activity, and published case reports show that it has been used to treat patients with serious infections caused by a wide variety of DNA viruses. For example, patients with acyclovir- and foscarnet-resistant HSV infection have been treated successfully with topical and systemic cidofovir.[74,317,325,327] It also may be effective in treatment of selected patients with acyclovir-resistant VZV infections.[486] Moreover, one report showed that treatment with cidofovir and anti-CD20 monoclonal antibody was associated with remission and regression of posttransplantation EBV-associated lymphoproliferative disease.[217] The use of cidofovir to treat patients with AIDS and HHV-8 viremia and disease also has been reported.[62,365] Human papillomavirus–induced epithelial cell proliferation may be responsive to treatment with topical and intralesional administration of cidofovir. Several small, uncontrolled case series have described the successful use of cidofovir to treat juvenile laryngeal papillomatosis, hypopharyngeal and esophageal papillomatous lesions, anogenital condylomas, and cervical intraepithelial neoplasia.* Furthermore, intravenous and intralesional therapy with cidofovir has been used to treat individual patients, including children, with refractory disseminated respiratory papillomatosis of the lung.[20,345,355] Human BK polyomavirus–associated acute hemorrhagic cystitis in immunocompromised patients has been treated with cidofovir, with varying results.[36,163] Case reports and small clinical trials evaluating cidofovir treatment in patients with progressive multifocal leukoencephalopathy who have AIDS or other immunocompromising conditions have not shown consistent benefit in survival or sustained improvement in neurologic status.† Successful cidofovir treatment of adenovirus disease in marrow and stem cell transplant recipients has been published in reports of case series, with the best results noted in patients in whom the disease was localized and treatment was initiated early.‡ Controlled clinical trials evaluating eye drops containing an investigational topical solution of cidofovir to treat patients with acute keratoconjunctivitis caused by adenovirus have not shown consistent benefit in the doses used.[245,246] Poxviruses are inhibited by cidofovir in concentrations safely achievable in humans, and at least one case report of successful treatment of orf (ecthyma contagiosum) has been published.[17,188] In addition, in vitro and animal model data suggest that cidofovir may be effective in the treatment and short-term, postexposure prophylaxis of smallpox and other related poxvirus infections in humans as well as in the treatment of complications that may occur after inoculation with smallpox (vaccinia-like) vaccine.§ However, no clinical trials in humans to evaluate the efficacy of cidofovir for the treatment of poxvirus infections have been published.[398]

Dosage. The usually recommended dose for induction therapy with cidofovir is 5 mg/kg given as an intravenous infusion during the course of 1 hour administered once weekly for 2 consecutive weeks. Some clinicians suggest a reduced dosage regimen of 1 mg/kg administered three times weekly to reduce the risk of renal toxicity.[253] Maintenance therapy usually is administered as 1-hour infusions of 5 mg/kg once every 2 weeks to complete a total of at least five doses. These doses should be decreased to 1 to 3 mg/kg if renal insufficiency is present and discontinued if significant elevation of serum creatinine concentration or proteinuria occurs. Probenecid should be administered orally with each dose of cidofovir, 3 hours before and then 2 and 8 hours after completion of the intravenous infusion. Prehydration with normal saline before each infusion also is recommended. Topical preparations of eye drops containing 0.2 to 1 percent cidofovir and creams containing 1 percent cidofovir are being

investigated.[245,246] The usual concentration used for intralesional injection is 2.5 mg/mL.[310,355]

Adverse Effects. Cidofovir is nephrotoxic and produces clinically apparent proximal tubular dysfunction, including Fanconi syndrome and acute renal failure, in as many as half the patients who receive the drug.[373,454] Early laboratory signs of renal toxicity include proteinuria, glycosuria, azotemia, and metabolic acidosis. Therefore, patients receiving cidofovir should have a urinalysis and serum tests for renal function performed before taking each dose. The risk for development of renal toxicity can be reduced but not eliminated by probenecid and saline prehydration. Moreover, renal toxicity is more likely to occur if other nephrotoxic agents, such as aminoglycosides, amphotericin B, or foscarnet, are administered concurrently with cidofovir.[577] In clinical trials of patients with AIDS, administration of cidofovir also was associated with neutropenia. Ocular toxicity, including ocular hypotony (decreased intraocular pressure) and anterior uveitis and iritis, also has been reported in patients receiving cidofovir therapy.[4] Therefore, frequent monitoring by an ophthalmologist, including measurement of intraocular pressure, is recommended for patients receiving cidofovir therapy. Intravitreal administration of cidofovir has produced uveitis, vitreitis, reduced intraocular pressure, and loss of vision.[311,394] Local or topical treatment with cidofovir may produce local reactions in the skin.

CHAPTER 239

Antifungal Agents

Andreas H. Groll • Thomas J. Walsh

Invasive fungal infections are important causes of morbidity and mortality in children with severe underlying illnesses. These infections remain difficult to diagnose and can be rapidly fatal. As a consequence, early and appropriate antifungal chemotherapy is pivotal for successful management and survival. For more than two decades, options for antifungal chemotherapy were limited to amphotericin B deoxycholate (AmB-D) with or without the addition of flucytosine. The 1990s, however, witnessed major progress through the introduction of fluconazole and itraconazole and the development of less toxic formulations of amphotericin B. More recent advances include the advent of novel, potent, and broad-spectrum antifungal triazoles and the clinical development of echinocandins, an entirely new class of antifungal agents that target the fungal cell wall (Fig. 239-1). This chapter is devoted to the clinical pharmacology of systemic antifungal agents; emphasis is placed on pharmacokinetics, dosing, and safety in pediatric age groups.

AGENTS FOR TREATMENT OF INVASIVE MYCOSES

Polyene Antibiotics

Amphotericin B Deoxycholate

First isolated in the 1950s as a natural product of a soil actinomycete,[192] amphotericin B belongs to a family of approximately 200 polyene macrolide antibiotics and consists of seven conjugated double bonds, an internal ester, a free carboxyl group, and a glycoside side chain with a primary amino group (Fig. 239-2). The compound is amphoteric (capable of reacting as either an acid or a base), not orally or intramuscularly absorbed, and virtually insoluble in water. For parenteral use, amphotericin B has been solubilized with deoxycholate as a micellar suspension, and this formulation has been available for more than 50 years.[48]

Mechanism of Action. Amphotericin B, similar to other polyenes, acts primarily by binding to ergosterol, the principal sterol in the cell membrane of most fungi. This interaction with ergosterol results in the formation of ion channels, loss of protons and monovalent cations, depolarization, and concentration-dependent cell death. Although with less avidity, the compound also binds to cholesterol, the main sterol of mammalian cell membranes; this action accounts for most of the toxicities associated with this drug. A second mechanism of action of amphotericin B may involve oxidative damage of the cell through a cascade of oxidative reactions linked to its own oxidation, with formation of free radicals or an increase in membrane permeability. In addition to its antifungal activity, amphotericin B and its lipid formulations differentially augment innate host defense mechanisms against fungal pathogens.[75,142,208,510,511]

Antifungal Activity. Amphotericin B has a broad spectrum of antifungal activity that includes most fungi pathogenic in humans. True microbiologic resistance to antifungal polyenes has been associated with qualitative or quantitative differences in the sterol composition of the cell membrane, but this resistance also may be related to increased catalase activity with decreased susceptibility to oxidative damage.[208] Resistance to amphotericin B remains uncommon in *Candida* spp. other than *Candida lusitaniae*, *Candida guilliermondii*, and *Candida lipoyltica*. Some isolates of *Candida glabrata*, *Candida parapsilosis*, and *Candida tropicalis* also may be resistant to amphotericin B.[560,579,612] *Aspergillus terreus*[265,528] and some of the emerging pathogens such as *Trichosporon asahii*,[12,585,586] *Fusarium* spp.,[73,456] *Scedosporium apiospermum*,[541,588] *Scedosporium prolificans*,[57,338] and certain dematiaceous fungi[203] may be completely resistant to safely achievable serum concentrations of amphotericin B. Acquisition of secondary resistance is an uncommon occurrence and has not been a clinical problem.[207]

Pharmacodynamics. In time-kill studies, amphotericin B displays concentration-dependent fungicidal activity against susceptible *Candida albicans*, *Cryptococcus neoformans*, and *Aspergillus fumigatus*.[289,290,451] In addition to its concentration-dependent fungicidal dynamics, a prolonged postantifungal effect (PAFE) of amphotericin B of up to 12 hours' duration has been demonstrated in *C. albicans* and *C. neoformans*.[158,550] Studies in laboratory animals support the concentration-dependent kill kinetics of amphotericin B in vitro. In neutropenic pharmacokinetic and pharmacodynamic mouse models of disseminated candidiasis and pulmonary aspergillosis, peak plasma concentration (C_{max})/minimal inhibitory concentration (MIC) was the parameter that provided the best correlation with outcome as measured by the residual organismal burden in tissue.[26,610] These laboratory findings indicate that single daily doses rather than continuous infusion will be most effective. Therefore, the

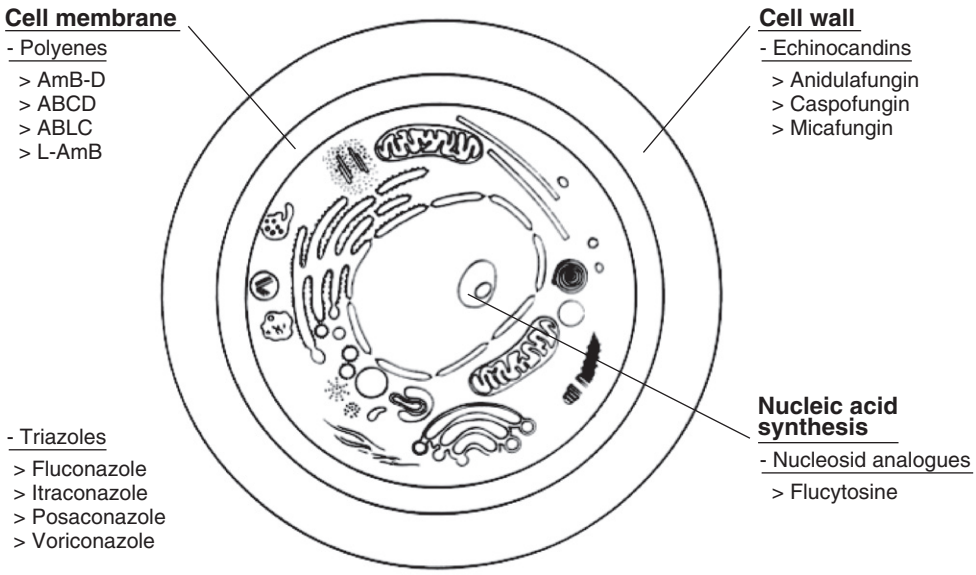

FIGURE 239-1 ■ Cellular targets of approved antifungal agents for treatment of invasive mycoses. (Modified from Groll AH, Piscitelli SC, Walsh TJ. Antifungal pharmacodynamics: concentration-effect relationships in vitro and in vivo. *Pharmacotherapy* 2001;21[suppl 8]:133-48.)

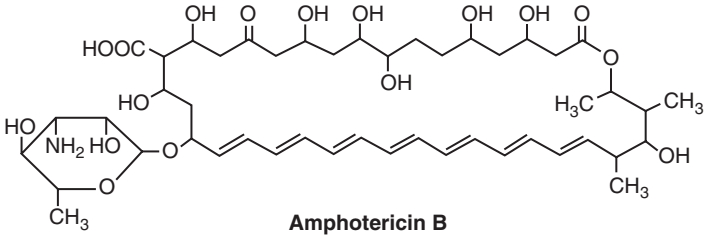

FIGURE 239-2 ■ Structural formula of amphotericin B.

dosage of amphotericin B should not be uncritically reduced, and infusion for durations longer than that recommended by the manufacturer should be avoided.

Pharmacokinetics. After intravenous administration, amphotericin B rapidly dissociates from its carrier and becomes highly protein-bound before distributing into tissues.[101] The disposition of the compound follows a three-compartment model, with rapid initial clearance from plasma followed by a biphasic pattern of elimination with a β half-life of 24 to 48 hours and a prolonged terminal (γ) half-life of 15 days or more.[36] Tissue levels of amphotericin B in laboratory animals are highest in liver, spleen, bone marrow, kidney, and lung; concentrations in body fluids other than plasma are generally low.[266,317] However, despite mostly undetectable concentrations in the cerebrospinal fluid (CSF) and comparatively low concentrations in brain tissue across all species, amphotericin B is effective in the treatment of fungal infections of the central nervous system (CNS). No metabolites of amphotericin B have been identified. Approximately 10 percent of parent compound is excreted into urine and bile, a finding suggesting that tissue accumulation accounts for most of the disposition of drug.[49,50,119,461] Accordingly, adjustment of dose is not necessary in patients with unrelated renal or hepatic dysfunction.

Reported pharmacokinetic data in pediatric age groups are characterized by a high interindividual variability, which may be related to differences in underlying diseases and modes of administration (Table 239-1).[40,55,297,389,522] However, infants and children appear to clear the drug from plasma more rapidly than do adults, as indicated by a negative correlation between age and clearance.[55,297,388] Because distribution into tissues appears to be the main route of clearance from plasma, the faster clearance in individuals of younger age may be explained by the larger relative volume of parenchymatous organs in contrast to that in adults.[379] Currently, dosage recommendations for all pediatric age groups do not differ from those in adult patients.

Adverse Effects. Infusion-related reactions and dose-limiting nephrotoxicity are major problems associated with the use of AmB-D and often limit successful therapy. Infusion-related reactions (i.e., fever, rigors, chills, myalgias, arthralgias, nausea, vomiting, and headaches) are thought to be mediated by the release of cytokines from monocytes in response to the drug.[30] These reactions can be noted in as many as 73 percent of patients prospectively monitored at the bedside.[578] In a prospective interventional study of pediatric patients with cancer, investigators observed fever, rigors, or both, associated

TABLE 239-1 **Pharmacokinetic Parameters of Amphotericin B Deoxycholate in Pediatric Patients***

Population/Reference	Dosage (mg/kg)	C_{max} (μg/mL)	$AUC_{0-\infty}$ (μg/mL/hr)	Vd_{ss} (L/kg)	Cl (L/hr/kg)	$t_{1/2}$ (hr)

with the infusion of amphotericin B in 19/78 treatment courses (24%).[389] However, these characteristic adverse effects of amphotericin B are observed only rarely in the neonatal setting.[286] In clinical practice, infusion-related reactions associated with amphotericin B therapy may be blunted by slowing the infusion rate but often require premedication with acetaminophen 10 to 15 mg/kg, hydrocortisone 0.5 to 1 mg/kg, or meperidine 0.2 to 0.5 mg/kg.[579] Less common acute adverse effects are hypotension, hypertension, flushing, and vestibular disturbances; bronchospasm and true anaphylaxis are rare occurrences.[207] Cardiac arrhythmias and cardiac arrest resulting from acute potassium release may occur with rapid infusion (<60 minutes), especially if the patient has preexisting hyperkalemia or renal impairment.[85,197,373]

The hallmarks of amphotericin B–associated dose-limiting nephrotoxicity are azotemia, wasting of potassium, and wasting of magnesium. Renal tubular acidosis and impaired urinary concentration ability rarely are of clinical significance.[194,489] Relevant electrolyte wasting occurs in approximately 12 percent of prospectively monitored patients.[578] Hypokalemia can be quite refractory to replacement until hypomagnesemia is corrected.[489] Azotemia is a common occurrence. In a large prospective clinical trial, the baseline serum creatinine rose by more than 100 percent in 34 percent of 344 unstratified pediatric and adult patients receiving amphotericin B for empirical therapy of fever and neutropenia.[578] Azotemia can be exacerbated by concomitant nephrotoxic agents, in particular by cyclosporine and tacrolimus.[607] In series reporting safety data of amphotericin B 0.5 to 1 mg/kg in premature neonates, the incidence of azotemia ranged from zero to 15 percent,[84,190,286,319,322] a finding indicating that the compound is much better tolerated in this setting than reported early during its use.[39]

Nephrotoxicity associated with the use of amphotericin B has the potential to lead to renal failure and dialysis[614]; however, azotemia usually is reversible after discontinuation of the drug.[152,319,579] Avoiding concomitant nephrotoxic agents, appropriate hydration and normal saline loading (3 mEq Na^+/kg/day)[29,30,236] may greatly lessen the likelihood and severity of azotemia associated with amphotericin B therapy.

Other potentially relevant adverse effects of amphotericin B include demyelinizing encephalopathy[382] and normocytic, normochromic anemia associated with low erythropoietin levels after long-term administration.[120] Because amphotericin B deoxycholate is topically irritating, a central line should be used for infusion, and local instillation of amphotericin B should be considered only in conjunction with expert consultation.

Therapeutic Monitoring. Historically, 1-hour postinfusion plasma concentrations of twice the MIC of the fungal isolate have been proposed as targets for treatment of yeast infections.[150] However, monitoring of amphotericin B concentrations in plasma or CSF appears to be of little value because relationships between plasma and tissue concentrations and clinical efficacy or toxicity have not been adequately characterized.[207]

The toxicity of amphotericin B and the practice of normal saline loading warrant close monitoring of serum electrolytes, urea, and creatinine. The drug must not be infused in less than 60 minutes and only under particularly careful cardiac monitoring in newborns, as well as in patients with hyperkalemia and renal impairment, where arrhythmias resulting from acute potassium release may develop.[85,215]

Drug Interactions. Drug–drug interactions caused by shared metabolic pathways are unknown for amphotericin B. Hypokalemia may be aggravated by corticosteroids, cause rhabdomyolysis, and enhance the effects of nonpolarizing muscle relaxants. Similarly, hypomagnesemia may become especially profound in patients with cancer and platinum-associated nephropathy. Impairment of glomerular filtration by amphotericin B may enhance plasma levels and, thereby, toxicity of many renally cleared drugs, including aminoglycosides, vancomycin, fluorocytosine, and cyclosporine.[207] Finally, the

simultaneous infusion of granulocytes has been associated with acute pulmonary reactions[621] and therefore should be avoided.

Indications. With the exception of resource-limited settings, few indications are left for antifungal treatment of opportunistic mycoses with AmB-D. These indications include candidemia and acute tissue-invasive candidiasis, particularly in neonates, and induction therapy for cryptococcal meningitis; however, in the absence of adequate clinical trials, AmB-D is still a valid option for treatment of severe forms of the endemic mycoses (Tables 239-2 to 239-4). Depending on both the type of infection and the host, the recommended daily dosage ranges from 0.7 to 1 mg/kg/day administered over 2 to 4 hours as tolerated.[207]

For empirical antifungal therapy in the persistently febrile neutropenic host, the historical standard dosage has been 0.5 to 0.6 mg/kg/day.[162,441] Efficacy of prophylactic intravenous amphotericin B in the setting of anticancer therapy has not been documented,[209] and a large, randomized, multicenter study failed to show any preventive benefit of aerosolized amphotericin B in neutropenic patients at high risk for developing invasive mold infections.[498] However, aerosolized amphotericin B may have a preventive role in patients who have undergone lung transplantation.[145]

On principle, treatment should be started at the full target dose, with careful bedside monitoring during the first hour of infusion to allow for prompt intervention for infusion-related reactions.[579] With the exception of uncomplicated candidemia and induction therapy of cryptococcal meningoencephalitis, the duration of treatment is ill defined for most infections.

Amphotericin B Lipid Formulations

During the late 1990s, three novel formulations of amphotericin B were approved in the United States and most of Europe: AmB colloidal dispersion (ABCD, Amphocil, or Amphotec), AmB lipid complex (ABLC or Abelcet), and a small unilamellar liposomal formulation (L-AmB, AmBisome). Because of their reduced nephrotoxicity in contrast to AmB-D, these compounds allow for the safer delivery of higher dosages of the parent molecule (amphotericin B). However, data from animal models also suggest that higher dosages also are required for equivalent antifungal efficacy.[244,620]

Physicochemical Properties and Pharmacokinetics. The carriers of the lipid formulations are composed of biodegradable, amphiphilic bilayered membranes in which the hydrophilic heads of the lipid molecules face outward to shield the hydrophobic tails. The membranes may form either spherical vesicles termed liposomes or bilayered complexes or dispersions with no specific vesicular structure. Incorporated into these water-soluble carriers, amphotericin B becomes soluble in plasma and available for distribution. Each of the lipid formulations of amphotericin B possesses distinct physicochemical and pharmacokinetic properties. All three, however, preferentially distribute to organs of the mononuclear phagocytic system (MPS) and functionally spare the kidney. Although the micellar dispersion of ABCD behaves kinetically very similarly to AmB-D, the small unilamellar liposomal preparation has a prolonged circulation time in plasma, achieves strikingly high C_{max} and area under the concentration versus time curve (AUC) values, and is taken up only slowly by the MPS. In contrast, the

large, ribbon-like aggregates of ABLC are efficiently opsonized by plasma proteins and rapidly taken up by the MPS, thus resulting in lower peak plasma and AUC values (Table 239-5).[218,244] Whether and how the distinct physicochemical and pharmacokinetic features of each formulation translate into different pharmacodynamic properties in vivo are largely unknown. However, experimental head-to-head comparisons of all four formulations of amphotericin B against defined invasive mycoses suggest that important differences exist in antifungal efficacy depending on the agent, dose, type, and site of infection.[103,213,404]

Safety and Antifungal Efficacy. Safety and antifungal efficacy of ABCD, ABLC, and L-AmB were demonstrated in an array of phase II and III clinical trials in immunocompromised, mostly adult patients with a wide spectrum of underlying disorders.* The overall response rates in these trials ranged from 53 to 84 percent in patients with invasive candidiasis and 34 to 59 percent, respectively, in patients with presumed or documented invasive aspergillosis.[218,244] A few randomized, controlled trials were completed in which one of the newer formulations was compared with AmB-D. These studies consistently showed at least equivalent therapeutic efficacy and reduced nephrotoxicity of the investigated lipid formulation. Infusion-related side effects of fever, chills, and rigor were less frequent with L-AmB only.[17,578,606,608] Several individual cases of substernal chest discomfort, respiratory distress, and sharp flank pain may occur during infusion of L-AmB[273,465]; in comparative studies, hypoxic episodes associated with fever and chills occurred more frequently in ABCD recipients than in recipients of AmB-D.[74,606] Mild increases in serum bilirubin and alkaline phosphatase have been observed with all three formulations, as well as mild increases in serum transaminases with L-AmB. Nevertheless, no case of fatal liver disease has occurred.[218,244,620] An increased rate of hyperphosphatemia has been reported for L-AmB[291]; however, true hyperphosphatemia has to be carefully differentiated from pseudohyperphosphatemia that is due to interferences of L-AmB with assay systems for determination of serum phosphorous.[269]

Experience in Pediatric Patients. Considerable numbers of pediatric patients have been treated with ABCD, ABLC, or L-AmB on protocols in the clinical trials cited earlier.[524] Separately published pediatric data are discussed in the following subsections.

ABCD. ABCD is a complex of amphotericin B and sodium cholesteryl sulfate in an approximate 1:1 molar ratio that forms disklike colloidal structures on dissolution.[218] Estimated pharmacokinetic parameters in children are not significantly different from those in adult patients under conditions of steady state: mean AUC from 0 to 24 hours (AUC_{0-24}) is 7.10 mg/L/hr (normalized to a 1-mg/kg/day dose); mean volume of distribution (V_d) is 4.57 L/kg, and mean total clearance (Cl) is 0.144 L/hr/kg.[10]

A double-blind, randomized trial comparing ABCD (4 mg/kg/day) with AmB-D (0.8 mg/kg/day) for empirical antifungal therapy of febrile neutropenic patients that also included a larger number of pediatric patients found that ABCD was as effective but significantly less nephrotoxic than AmB-D.[606] Among children (0 to 15 years; mean, 8.8 years) with presumed or proved invasive fungal infections refractory to or intolerant of amphotericin B who were treated on five different open-label studies of ABCD with dosages that ranged from 0.8 to 7.5 mg/kg (mean, 4.5 mg/kg), 67 percent of patients reported infusion-related reactions, but nephrotoxicity, defined as an increase in serum creatinine to 2 times or more of the baseline value, was reported in only 12 percent.[484]

*References 110, 238, 312, 462, 471, 582, 607, 617.

The published experience in the neonatal setting is limited to 16 infants with very low birth-weight (779 ± 170 g; 25 ± 2 weeks) with invasive candidiasis and a serum creatinine concentration of 1.2 mg/dL or greater.[329] Infants received 3 mg/kg ABCD on day 1, followed by 5 mg/kg/day thereafter; a second agent was permitted for candidemia that persisted for 7 or more days. Of 14 evaluable patients, 13 cleared the organism after therapy with ABCD alone ($n = 8$) or in combination with another agent ($n = 5$), and overall survival was 75 percent.

These data overall indicate no fundamental differences in disposition, safety, and antifungal efficacy of ABCD in contrast to adult populations. The U.S. Food and Drug Administration (FDA)–approved indication is treatment of probable or proven invasive aspergillosis refractory to or intolerant of AmB-D, and the approved dosage is 3 to 4 mg/kg/day, administered over the course of 2 hours.

ABLC. ABLC is composed of dimyristoyl phosphatidylcholine/dimyristoyl phosphatidylglycerol (DMPC/DMPG) in a 1:1 molar ratio of lipid to amphotericin B and forms large, ribbon-like structures. The pharmacokinetic properties of ABLC were studied in whole blood in three pediatric patients with cancer who received the compound at 2.5 mg/kg over the course of 6 weeks for hepatosplenic candidiasis.[592] Steady state was achieved by day 7 of therapy; after the final dose, the mean $AUC_{0\text{-}24}$ was 11.9 ± 2.6 mg/L/hr, the mean C_{max} was 1.69 ± 0.75 mg/L, and clearance was 0.218 L/kg/hr. In the six patients evaluable for safety assessment, mean serum creatinine levels were stable at the end of therapy and at 1-month follow-up and no increase in hepatic transaminases occurred. Five of the patients had infusion-related reactions to the first dose, which were prospectively monitored without prior premedication; however, infusion-related adverse reactions were well controlled thereafter by conventional premedications. All evaluable patients responded to therapy.

Safety and antifungal efficacy of ABLC were studied in 111 treatment episodes in pediatric patients (21 days to 16 years of age) refractory to or intolerant of conventional antifungal agents through an open-label, emergency-use protocol in the United States.[590] ABLC was administered at a mean daily dosage of 4.85 mg/kg (range, 1.1 to 9.5 mg/kg/day) for a mean duration of 38.9 days (range, 1 to 198 days). The mean serum creatinine for the entire study population did not significantly change between baseline (1.23 ± 0.11 mg/dL) and cessation of ABLC therapy (1.32 ± 0.12 mg/dL) over 6 weeks. No significant differences were observed between baseline and end-of-therapy levels of serum potassium, magnesium, hepatic transaminases, alkaline phosphatase, and hemoglobin. Among 54 cases fulfilling criteria for evaluation of antifungal efficacy, a complete or partial therapeutic response was obtained in 38 patients (70%).

The safety and efficacy of ABLC also were assessed in 548 children and adolescents who were enrolled in the Collaborative Exchange of Antifungal Research registry. Most patients were either intolerant of or refractory to conventional antifungal therapy. Response data were evaluable for 255 of the 285 patients with documented single or multiple pathogens. A complete (cured) or partial (improved) response was achieved in 54.9 percent of patients. No significant difference was noted between the rates of new hemodialysis versus baseline hemodialysis. Elevations in serum creatinine of greater than 1.5 times baseline and greater than 2.5 times baseline values were seen in 24.8 and 8.8 percent of all patients, respectively. The overall response rate and safety profile in pediatric patients were consistent with earlier reported findings of smaller trials.[611]

Eleven infants aged 6 months and younger with candidemia were enrolled in the U.S. open-label, emergency-use protocol.[590] Of the 11 patients, 7 maintained a stable mean serum creatinine; in 4 patients, a rise in serum creatinine was observed, but in each case, the increase was less than 40 percent of the baseline value. No differences were observed between baseline and end-of-therapy mean bilirubin levels. Among the 8 evaluable infants, a complete response was observed in 6 (75%). A population pharmacokinetic study in 28 mostly premature neonates with invasive *Candida* infections demonstrated that the disposition of ABLC in neonates is similar to that observed in other age groups; weight was the only factor that influenced clearance.[622] The safety of ABLC in neonates is further supported by a retrospective case-control study in 35 infants with very low birth weight who received the compound for at least 2 weeks; treatment with ABLC was well tolerated and did not increase serum creatinine or decrease potassium.[37]

The current data suggest no fundamental differences in disposition, safety, and antifungal efficacy of ABLC in contrast to adults. The FDA-approved indication is treatment of invasive fungal infections refractory to or intolerant of AmB-D, and the approved dosage is 5 mg/kg/day administered over the course of 2 hours.

L-AmB. L-AmB consists of small, unilamellar spherical vesicles (true liposomes) composed of hydrogenated soy phosphatidylcholine and distearoyl phosphatidylglycerol stabilized by cholesterol and combined with amphotericin B in a 2:0.8:1:0.4 molar ratio.[218] The pharmacokinetic properties of L-AmB in pediatric patients beyond the neonatal period were investigated in a formal phase II, dose-escalation trial investigating dosages of 2.5, 5, and 7.5 mg/kg in immunocompromised patients, as well as by using a population-based approach. The results of these studies indicate that the disposition of L-AmB in pediatric patients is not substantially different from that in adults and that weight is a covariate that determines clearance and volume of distribution.[248,503] A pharmacokinetic pilot study was conducted in 12 children at risk for developing invasive fungal infections who received once-weekly, high-dose L-AmB (10 mg/kg over 2 hours) as prophylaxis. L-AmB was well tolerated and showed measurable amphotericin B plasma concentrations 7 days after the dose, a finding suggesting that once-weekly administration may provide useful protection against fungal infections.[360]

Many pediatric patients have been enrolled in clinical trials with L-AmB but have not been reported separately.[365,578] Two hundred four children (mean age, 7 years) with neutropenia and fever of unknown origin were randomized in an open-label, multicenter trial to receive conventional AmB-D at 1 mg/kg/day ($n = 63$), L-AmB at 1 mg/kg/day ($n = 70$), or L-AmB at 3 mg/kg/

day (n = 71) for empirical antifungal therapy.[445] Twenty-nine percent of patients treated with L-AmB 1, 39 percent of patients treated with L-AmB 3, and 54 percent of patients treated with AMBD experienced adverse effects (p = .01); nephrotoxicity, defined as 100 percent or more increase in serum creatinine from baseline, was noted in 8, 11, and 21 percent, respectively (not significant [NS]). Hypokalemia (<2.5 mmol/L) occurred in 10, 11, and 26 percent of patients, respectively (p = .02); increases in serum transaminase levels (≥110 U/L) occurred in 17, 23, and 17 percent, respectively (NS); and increases in serum bilirubin (≥35 μmol/L) occurred in 11, 12, and 10 percent of patients, respectively. L-AmB at either 1 or 3 mg/kg/day was significantly safer and at least equivalent to AMBD with regard to resolution of fever of unknown origin. L-AmB was well tolerated and effective in cohorts of immunocompromised children requiring antifungal therapy for proved or suspected infections, including patients with bone marrow transplants for primary immunodeficiencies[419] and patients with cancer.[463] A phase IV analysis of 141 courses of L-AmB administered for a mean of 17 days' duration at a mean maximum dosage of 2.5 mg/kg for various indications to pediatric patients with cancer and hematopoietic stem cell transplantation (HSCT) revealed a low rate of adverse events (4%), necessitating discontinuation. Whereas mean aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and bilirubin values were slightly higher at the end of treatment (p = .01), bilirubin and creatinine values were not different from baseline.[294]

L-AmB 2.5 to 7 mg/kg/day was evaluated prospectively in 24 infants with very low birth-weight (mean birth-weight, 847 ± 244 g; mean gestational age, 26 weeks) with systemic candidiasis. The mean duration of therapy was 21 days; the cumulative L-AmB dose was 94 mg/kg. Fungal eradication was achieved in 92 percent of the episodes; 20 (83%) infants were considered clinically cured at the end of treatment. No major adverse effects were recorded. One infant developed increased bilirubin and hepatic transaminase levels during therapy. Four (17%) infants died; in 2 of them (8%), the cause of death was attributed directly to systemic candidiasis.[276] In a second study undertaken by the same investigators, high-dose (5 to 7 mg/kg/day) L-AmB was evaluated prospectively in 41 episodes of systemic candidiasis occurring in 37 neonates (36/37 were premature infants with very low birth-weights). Twenty-eight, 5, and 8 infants received 7, 6 to 6.5, and 5 mg/kg/day, respectively. Median duration of therapy was 18 days; median cumulative dose was 94 mg/kg. Fungal eradication was achieved in 39/41 (95%) episodes. Fungal eradication was achieved more rapidly in patients treated early with high doses and in patients who received high-dose L-AmB as first-line therapy.[275] Further prospective[32] and retrospective[347] cohort studies attest to the safety of L-AmB in infants with very low birth-weight. Of note, the higher mortality reported in a single center analysis for infants with invasive candidiasis treated with lipid formulations relative to conventional AmB-D or fluconazole[34] is likely due to differences in acuity of illnesses and comorbidities rather than pharmacokinetic considerations.

Current data indicate no substantial differences in pharmacokinetics and pharmacodynamics of L-AmB between pediatric and adult patients. The FDA-approved dosages are 3 mg/kg/day (empirical antifungal therapy in febrile neutropenic patients), 3 to 5 mg/kg/day (therapy of invasive infections intolerant or refractory to AmB-D), and 6 mg/kg/day for cryptococcal meningitis, administered over the course of 2 hours. In Europe, L-AmB is approved for first-line treatment of invasive opportunistic mycoses.

Indications. The lipid formulations of AmB represent an important therapeutic advance in the management of invasive opportunistic fungal infections in immunocompromised patients. All three compounds have less renal toxicity than conventional amphotericin B, as defined by development of azotemia; distal tubular toxicity also may be somewhat reduced. Infusion-related reactions of fever, chills, and rigor appear to occur substantially less frequently only with L-AmB, and no new toxicities have been noted. The available pharmacokinetic and safety data from children so far indicate no fundamental differences from data obtained in the adult population.

Therapeutically, the lipid formulations are at least as effective as is conventional amphotericin B for treatment of most opportunistic human mycoses, and these formulations can be effective if conventional amphotericin B has failed. The specific clinical indications of the lipid formulations are discussed in the respective fungal disease chapters and are summarized in Tables 239-2 to 239-4.

Flucytosine

Flucytosine (5-fluorocytosine [5-FC]) is a low-molecular-weight, water-soluble, synthetic fluorinated pyrimidine analog (Fig. 239-3). It is taken up into the fungal cell by the fungus-specific enzyme cytosine permease and is converted in the cytoplasm by cytosine deaminase to 5-fluorouracil, a potent antimetabolite that causes RNA miscoding and inhibits DNA synthesis at the level of thymidylate synthase (Fig. 239-4).[144] Flucytosine is relatively nontoxic to mammalian cells because of the absence or very low level of activity of cytosine deaminase. In the United States, flucytosine is available only as an oral formulation; an intravenous formulation is available outside the United States in select countries.

Antifungal Activity. The antifungal activity of flucytosine in vitro is essentially limited to *Candida* spp., *C. neoformans*, *Cryptococcus gattii*, *Saccharomyces cerevisiae*,

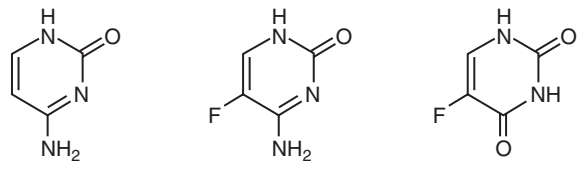

FIGURE 239-3 ■ Structural formulas of cytosine, flucytosine, and fluorouracil.

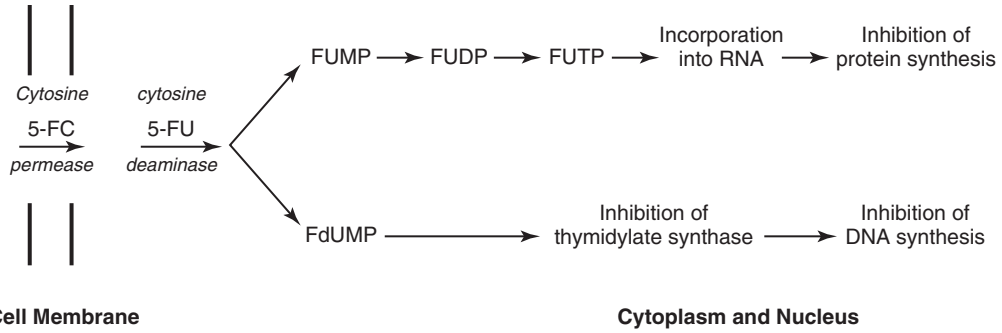

FIGURE 239-4 ■ Schematic of intracellular pathways and mechanism of action of flucytosine. *5-FC,* Flucytosine; *FdUMP,* 5-fluorodeoxyuridine monophosphate; *5-FU,* 5-fluorouracil; *FUDP,* 5-fluoridine diphosphate; *FUMP,* 5-fluoridine monophosphate; *FUTP,* 5-fluoridine triphosphate. (Modified from Groll AH, Piscitelli SC, Walsh TJ. Antifungal pharmacodynamics: concentration-effect relationships in vitro and in vivo. *Pharmacotherapy* 2001;21[suppl. 8]:133-48; and Vermes A, Guchelaar HJ, Dankert, J. Flucytosine: a review of its pharmacology, clinical indications, pharmacokinetics, toxicity and drug interactions. *J Antimicrob Chemother* 2000;46:171-9.)

Rhodotorula spp., and some dematiaceous molds.* Flucytosine generally is thought to have no or weak activity against *Aspergillus* spp. and other hyaline molds,[181,349] although this lack of activity in vitro may be pH-dependent[530] and does not correlate with the documented efficacy in animal models.[532] Notably, whereas *Candida krusei* appears to be less susceptible to flucytosine, the compound is highly active against *C. glabrata*.[144,170,433] Synergistic or additive effects in combination with amphotericin B have been observed against *Candida*[359,375] and *Aspergillus* spp.[531] and in combination with amphotericin B, fluconazole, voriconazole, and posaconazole against *C. neoformans*.[43,229,358,395,500] Combination with echinocandins was additive or indifferent in vitro against *Candida* spp.[278]

Two mechanisms of resistance have been reported: (1) mutations in enzymes necessary for cellular uptake and transport of flucytosine or its metabolism and (2) increased synthesis of pyrimidine that competes with the fluorinated antimetabolites of the compound.[139,567] In pretreatment isolates, intrinsically resistant strains have been found in 3 to 8 percent of *C. albicans*, in 0 to 8 percent of non-*albicans Candida* spp., and in 2 percent or fewer of *C. neoformans* isolates.[358,433] In an analysis of 8803 clinical isolates comprising 18 *Candida* spp. obtained from more than 200 medical centers worldwide, primary resistance to flucytosine was an uncommon occurrence among *Candida* spp. (95% sensitive, 2% intermediate, and 3% resistant), with the exception of *C. krusei* (5% sensitive, 67% intermediate, and 28% resistant).[433] Development of resistance to flucytosine can be observed during treatment,[170] and it is thought to be caused predominantly by selection of resistant clones.[567] As a consequence, flucytosine is rarely given alone but instead is given in combination with amphotericin B or fluconazole.

Pharmacodynamics. Time-kill assays against *Candida* spp. and *C. neoformans* demonstrated a predominantly concentration-independent fungistatic (99% reduction in colony-forming units) activity of flucytosine at concentrations exceeding the MIC of the investigated isolates.[325,556] A prolonged PAFE against these organisms was noted consistently that was dependent on concentration and duration of exposure and ranged from 0.8 to 10 hours.[367,491,492,626] Investigation of pharmacokinetic and pharmacodynamic relationships in a neutropenic mouse model of disseminated candidiasis that used the residual fungal burden in kidney tissue as the end-point of antifungal efficacy revealed that both the time above the MIC and the AUC/MIC ratio were important in predicting efficacy; maximal efficacy was observed when levels exceeded the MIC for only 20 to 25 percent of the 24-hour dosing interval.[19] In experiments that used a pharmacodynamic model of disseminated candidiasis and bridging to humans by population pharmacokinetics and Monte Carlo simulation, an in vivo drug exposure breakpoint for flucytosine was apparent when serum levels were greater than the MIC for 45 percent of the dosing interval. The Monte Carlo simulations suggested that, using a human dose of 100 mg/kg/day in four divided doses, flucytosine resistance was defined at an MIC of 32 mg/L. Target attainment rates after administration of 25, 50, and 100 mg/kg/day were similar.[253] These data collectively suggest that lower dosages or less frequent dosing may yield identical antifungal efficacy while further reducing potential toxicities of flucytosine that are thought to be concentration-dependent.[170]

Pharmacokinetics. Flucytosine is absorbed readily from the gastrointestinal tract, and oral bioavailability exceeds 80 percent (Table 239-6). C_{max} occurs 1 to 2 hours after administration. As a water-soluble compound, flucytosine has negligible protein binding (4%) and is widely distributed in the body, with a volume of distribution that approximates that of total body water. Mean CSF concentrations usually are 65 to 90 percent of simultaneous plasma concentrations. The drug penetrates well into peritoneal fluid, inflamed joints, and other fluid compartments, including the eye.[65,120,207]

In humans, less than 1 percent of a given dose of flucytosine is thought to undergo hepatic metabolism.[341] Some evidence suggests that bacteria of the gastrointestinal flora deaminate flucytosine to resorbable

5-fluorouracil,[231,342] a finding that may account for some of the toxicities observed after oral administration of the drug. Approximately 95 percent of a given dose of flucytosine is excreted into the urine in unchanged, active form by simple glomerular filtration.[207] Because the compound's elimination parallels the glomerular filtration rate, adjustment of the dosage is necessary in patients with impaired renal function.[122] In patients undergoing hemodialysis, a dose of 37.5 mg/kg is recommended after dialysis; in those undergoing hemofiltration, the dosage needs to be adjusted to the individual filtration rate.[264,315] In peritoneal dialysis, the compound can be administered systemically or intraperitoneally.[366] Although the data are limited, impaired liver function does not appear to alter the disposition of flucytosine.[120]

In infants and children, the pharmacokinetic properties of flucytosine have not been systematically characterized. However, because of very similar physicochemical and pharmacokinetic properties, developmental changes in disposition similar to those found with fluconazole can be anticipated. Indeed, a similarly marked interindividual variability in clearance and volume of distribution has been reported in neonates[40] that renders uniform dosing recommendations in this population impossible.

A starting dosage for both adults and children of 100 mg/kg daily divided into three or four doses is recommended currently. Monitoring of plasma concentrations is essential to adjust dosage to changing renal function and avoid toxicity. After oral administration, near peak levels 2 hours after dosing overlap with trough levels as patients reach steady state, and thus these levels are sufficient for therapeutic monitoring.[170] In practice, plasma levels between 40 (trough) and less than 100 mg/L (peak) correlate with antifungal efficacy and seldom are associated with hematologic adverse effects.[170,568] However, retrospective evaluations in the United Kingdom revealed that only a fraction of plasma levels ordered for therapeutic monitoring were in this concentration range.[420,520]

Adverse Effects. Common adverse effects associated with flucytosine that occur in 5 to 6 percent of patients include gastrointestinal intolerance and reversible elevations of hepatic transaminases and alkaline phosphatase. Rarer side effects are skin rashes, blood eosinophilia, and crystalluria.[207] Hematologic adverse effects have been reported in overall 6 percent of patients receiving oral flucytosine and may include neutropenia, thrombocytopenia, or pancytopenia. Notably, hematologic adverse effects occur less frequently if plasma levels of flucytosine do not exceed 100 mg/L.[170,207]

Drug Interactions. Orally administered, nonresorbable antibiotics and administration of aluminum-based or magnesium hydroxide–based antacids may delay but do not impair absorption of the compound from the gastrointestinal tract.[207] 5-FC undergoes only minor hepatic metabolism, and it is not known to interfere with the cytochrome P (CYP)450 enzyme system. However, any drug that can cause a reduction in the glomerular filtration rate may lead to increased flucytosine serum levels and thereby has the potential to enhance 5-FC–associated toxicity. This phenomenon almost invariably is encountered with concomitant administration of amphotericin B, but it can occur similarly with numerous antimicrobial agents, anticancer drugs, and cyclosporine, to name only the most common examples.[120] The anticancer drug cytosine arabinoside (Ara-C) competitively inhibits the action of 5-FC, and these drugs should not be given concomitantly.[88]

Clinical Indications. Because of the propensity of susceptible organisms to develop resistance in vitro,[442] 5-FC traditionally is not administered as a single agent. Ample laboratory and clinical experience exists regarding the combination of amphotericin B deoxycholate and 5-FC (see Table 239-2).[144,207,567] Randomized clinical trials established the use of amphotericin B in combination with 5-FC as standard for induction therapy of cryptococcal meningitis in non–human immunodeficiency virus (HIV)-infected and HIV-infected patients.[54,557] Indeed, a small but well-designed trial demonstrated that the clearance of cryptococci from the CSF was significantly faster with amphotericin B in combination with 5-FC than with amphotericin B alone, amphotericin B in combination with fluconazole, or triple therapy, a finding confirming that the combination is the most rapidly fungicidal regimen.[78]

Although no comparative trials have been performed, the cumulative clinical experience supports the combination of amphotericin B with 5-FC for the treatment of *Candida* infections involving deep tissues, particularly in critically ill patients and when non-*albicans* *Candida* spp. are involved.[170,255,350,534] This includes *Candida* meningitis, endophthalmitis, endocarditis, vasculitis, and peritonitis, as well as osteoarticular, renal, and disseminated candidiasis.[207,579]

The combination of 5-FC with fluconazole is an option for cryptococcal meningitis, when treatment with conventional or liposomal amphotericin B is not feasible.[314,368,369,399] This combination also may be useful as second-line therapy for individual patients with invasive *Candida* infections involving aqueous body compartments.

Antifungal Triazoles

The antifungal azoles are a class of synthetic compounds that have one or more azole rings and—attached to one of the nitrogen atoms—a more or less complex side chain. Whereas the imidazoles have two nitrogen atoms, the triazoles have three in the five-member ring. The triazole ring confers improved resistance to metabolic degradation, greater target specificity, and an expanded spectrum of activity.[198,199] The imidazoles miconazole and ketoconazole were the first azole compounds developed for systemic treatment of human mycoses. Severe toxicities associated with the drug carrier (miconazole) and erratic absorption and significant interference with the human CYP450 system (ketoconazole), however, limited their clinical usefulness.[207] The triazoles fluconazole and itraconazole (Fig. 239-5), in contrast, have become extremely useful components of the antifungal armamentarium. Overall, they are well tolerated and possess a broad spectrum of activity. Whereas fluconazole and itraconazole have been available since the 1990s, a new generation of antifungal triazoles has entered clinical practice more recently; these so-called second-generation triazoles include voriconazole and posaconazole (Fig. 239-6).[247]

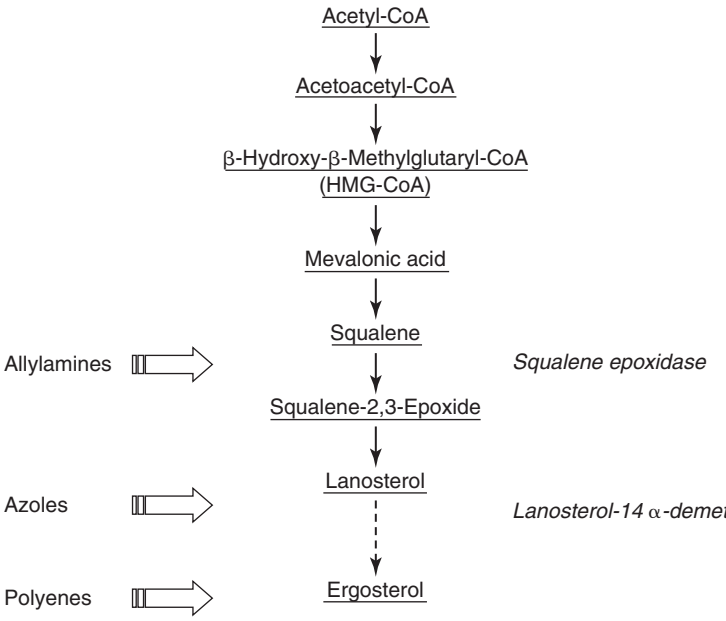

FIGURE 239-7 ■ Ergosterol biosynthesis and targets of current antifungal agents. *CoA,* Coenzyme A. (Modified from Groll AH, Walsh TJ. Uncommon opportunistic fungi: new nosocomial threats. *Clin Microbiol Infect* 2001;7[suppl 2]:8-24.)

Mechanism of Action. The antifungal azoles, as a class, target ergosterol biosynthesis by inhibiting the fungal CYP450-dependent enzyme lanosterol 14-α-demethylase. This inhibition interrupts the conversion of lanosterol to ergosterol and thus leads to accumulation of aberrant 14-α-methylsterols and depletion of ergosterol in the fungal cell membrane (Fig. 239-7). These effects alter cell membrane properties and function and, depending on organism and compound, may lead to cell death or inhibition of cell growth and replication. In addition, the azoles also inhibit CYP450-dependent enzymes of the fungal respiration chain, but the contribution of this action to their overall activity is unclear. Interaction with structurally similar mammalian CYP450-dependent enzyme systems is responsible for most toxicities and drug interactions of this class of compounds.[207,559]

Antifungal Activity. Fluconazole and itraconazole are active principally against dermatophytes, *Candida* spp., *C. neoformans*, *C. gattii*, *T. asahii*, and other uncommon yeast organisms, as well as against dimorphic fungi such as *Histoplasma capsulatum*, *Coccidioides* spp., *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, and *Sporothrix schenkii*.[198,199,544] These drugs have less activity against *C. glabrata* and none against *C. krusei*.[207,459] Clinically useful activity against *Aspergillus* spp. and dematiaceous molds is restricted to itraconazole, and both itraconazole and fluconazole are considered inactive against *Fusarium* spp. and the Mucorales.[207] The second-generation triazoles voriconazole and posaconazole have enhanced target activity and are active against a wide spectrum of clinically important fungi, including *Candida* spp., *T. asahii*, *C. neoformans*, *Aspergillus* spp., *Fusarium* spp., and other hyaline molds, as well as dematiaceous and dimorphic molds.* In contrast to fluconazole and itraconazole, both agents are active against *C. glabrata* and *C. krusei;* posaconazole also is active against some genera of the order Mucorales, a feature that distinguishes it from all current azole compounds.[202]

Resistance. Several mechanisms of azole resistance in *Candida* spp. have been identified and include, but are not limited to, molecular alterations at the target binding site, increased target expression, and induction of cellular efflux pumps.[45,427,485,608] In contrast to pathogenic bacteria, genetic exchange mechanisms are largely unknown in fungi. Exposure-induced cumulative molecular events that lead to stable azole resistance have been reported; however, in the clinical setting, resistance is encountered most commonly in the form of a primarily resistant species or through selection of resistant subclones during exposure to azoles.[459,608]

Acquisition of microbiologic and clinical azole resistance was reported first in patients with chronic mucocutaneous candidiasis who were receiving long-term therapy with ketoconazole.[256] In the 1990s, before the advent of highly active antiretroviral therapy, azole-resistant oropharyngeal and esophageal candidiasis became a major clinical conundrum in patients with advanced HIV infection.[453,470] Emergence of *C. glabrata* and *C. krusei* infections in association with fluconazole prophylaxis has been observed in several bone marrow transplant centers[267,355,615,616] and in large cancer centers.[296] However, a large prospective series from Seattle showed an altogether low incidence of breakthrough candidemia (4.6%; in two thirds caused by *C. glabrata* or *C. krusei*) and a low attributable mortality (20%) in patients receiving fluconazole prophylaxis despite frequent colonization with fluconazole-resistant *Candida* spp.[355] Although cross-resistance of *Candida* spp. to antifungal azoles is a common occurrence,[46,193,383,422] it is not obligate; for example, patients with microbiologic and clinical fluconazole-resistant mucosal candidiasis may respond to itraconazole or second-generation triazoles.[235,477]

*References 6, 96, 99, 102, 207, 247.

Nonetheless, patients who have been exposed to azoles and who have breakthrough candidemia or an azole-resistant *Candida* isolate have a high likelihood of cross-resistance, and treatment with alternative agents is advised.[340,412] Acquired resistance to azoles has been documented in patients with *C. neoformans* meningitis[63,512,513] and increasing reports are being published of secondary azole resistance and azole cross resistance in filamentous fungi, especially *Aspergillus* spp.*

Fluconazole

Fluconazole is a synthetic, low-molecular-weight, water-soluble *bis*-triazole (see Fig. 239-5). In contrast to ketoconazole, the compound has similar potency at the target enzyme but is much more specific and therefore better tolerated. Fluconazole is active against *Candida* spp., *C. neoformans*, *C. gattii*, *T. asahii*, and endemic dimorphic fungi, but not against *Aspergillus* spp. and other hyaline or dematiaceous molds. Fluconazole has intermediate activity against *C. glabrata* and is inactive against *C. krusei*.[191,199,434,544]

Pharmacodynamics. Fluconazole generally is considered to be a fungistatic agent.[208] Time-kill assays performed over incubation periods of 24 to 48 hours in susceptible *Candida* spp. and *C. neoformans* showed fungistatic activity of fluconazole with variable concentration-related growth effects.[82,83,134,289,290] However, time-kill studies that used extended periods of incubation up to 14 days and nonproliferating growth conditions demonstrated direct fungicidal activity of fluconazole against *C. albicans*.[519] These observations raise the possibility that fluconazole may ultimately be able to eliminate *Candida* spp. without help from host defenses. In serum-free growth media, fluconazole displays no measurable PAFE against *C. albicans* and *C. neoformans*, but concentration-dependent PAFEs of 1 to 3.6 hours were observed in the presence of fresh serum. Finally, pretreatment of *C. albicans* with fluconazole increased its vulnerability to killing by polymorphonuclear leukocytes.[158,369]

In vivo pharmacodynamic studies of fluconazole in murine models of disseminated *C. albicans* candidiasis using the fungal burden in kidney tissue as an end point for antifungal efficacy collectively suggested that the AUC/MIC ratio is the pharmacodynamic parameter that best predicts antifungal efficacy of fluconazole[18,334,521] and that dosing regimens that produce prolonged sub-MIC concentrations are associated with development of resistance.[23] The linear pharmacokinetics and the available experimental and clinical data are in support of once-daily dosing regimens. Pharmacodynamic models and several animal studies demonstrate a correlation between the MIC of fluconazole and antifungal efficacy.† A more recent analysis of 1295 patient-episode-isolate events from 12 published clinical studies demonstrates success rates of 85 percent for those episodes in which the fluconazole MIC was 8 mg/L or less, 67 percent for those episodes in which the MIC was 16 to 32 mg/L, and 42 percent for those episodes with isolates that had an MIC of 64 mg/L or higher.[428] Of note, the additional consideration of wild-type MIC distributions and epidemiologic cutoff values has led to the proposition of species-specific clinical breakpoints that may be more sensitive to detect emerging resistance to common *Candida* species.[430]

Pharmacokinetics. Fluconazole is formulated for oral and parenteral use, and its disposition is independent of route and formulation. Fluconazole exhibits linear plasma pharmacokinetics that fit best into a two-compartment open model.[77]

Independent of food or intragastric pH, the oral bioavailability of fluconazole is greater than 90 percent. C_{max} occurs 1 to 2 hours after ingestion. Multiple dosing increases C_{max} approximately 2.5-fold. Steady state generally is reached within 4 to 7 days after once-daily dosing, but it can be achieved rapidly by doubling the dose on the first day.[191,199] Because of the free solubility in water of this drug, protein binding is low. Fluconazole distributes well into virtually all tissue sites and body fluids. The ratio of CSF and serum concentrations ranges from 0.5 to 0.9 during the dosing interval, and penetration into brain tissue and the different compartments of the eye is excellent. Fluconazole is relatively stable to metabolic conversion; more than 90 percent of a dose is excreted by the kidney, with approximately 80 percent recovered as unchanged, active drug and 11 percent recovered as inactive metabolites.[77,191,199] Because excretion of fluconazole parallels the glomerular filtration rate, the dosage must be adjusted in patients with renal impairment. A 50 percent reduction is required in patients with a creatinine clearance of 50 mL/minute or less, and a 75 percent reduction is required in patients with a creatinine clearance of less than 21 mL/min; the initial loading dose need not be adjusted.[59,199] Fluconazole is dialyzable; in patients undergoing hemodialysis, 100 percent of the target dose is given after each dialysis session. In continuous venovenous hemofiltration and hemodiafiltration, dosing at the higher end of the dosing range (i.e., 800 mg/day in adults) is suggested.[58,496] A dose of 150 mg in a single 2-L dialysate bag has been used for continuous ambulatory peritoneal dialysis.* Hepatic insufficiency per se does not require adjustments of dosing, but careful monitoring of additional hepatic toxicity is required.[472] Finally, infants requiring extracorporeal membrane oxygenation (ECMO) were shown to have a higher volume of distribution but similar clearance relative to controls not on ECMO and may require higher doses for treatment.[597]

The plasma pharmacokinetic properties of fluconazole in pediatric age groups reflect developmental changes in the volume of distribution and clearance that are characteristic for a highly water-soluble drug with minor metabolism and predominantly renal elimination (Table 239-7). Except for premature neonates, in whom clearance initially is decreased, pediatric patients tend to have an increased weight-normalized clearance rate from plasma that leads to a shorter half-life in contrast to that

in adults.* Whereas population-based pharmacokinetic studies do not exist for children, gestational age at birth, postnatal age, and creatinine level were identified as parameters of impact on clearance of fluconazole in premature infants.[573,574] Because exposure over the course of time appears to be the most predictive pharmacodynamic parameter,[18,334] fractionating the dose is not required in infants and children, despite the shorter half-life in these age groups.

Adverse Effects. In adults, fluconazole has been administered safely over prolonged periods at dosages of up to 1200 mg/day; dose-escalation to 1600 mg/day resulted mainly in increased hepatotoxicity, and dose-limiting neurotoxicity was observed at 2000 mg/day.[15] Compiled data from adult patients who received the drug at dosages of 100 to 400 mg/day over the course of at least 7 days indicate an overall incidence of at least possibly related adverse effects of 16 percent; significant adverse effects or laboratory abnormalities leading to the discontinuation of the drug were noted in overall 2.8 percent.[199] Nausea, vomiting, and other gastrointestinal symptoms are seen in fewer than 5 percent and skin rashes and headaches in fewer than 2 percent and usually reversible; asymptomatic hepatic transaminase elevations were reported in as many as 7 percent of adult patients.[105,199]

In pediatric patients of all age groups, at dosages up to 12 mg/kg/day, fluconazole generally is well tolerated. The most common reported side effects in pediatric patients include gastrointestinal disturbances (8%), increases in hepatic transaminases (5%), and skin reactions (1%); toxicity-related discontinuation of therapy with fluconazole occurs in approximately 3 percent of patients.[398] Severe side effects, including severe hepatotoxicity and exfoliative skin reactions, have been rarely reported in association with fluconazole therapy.[105,206]

Drug Interactions. Fluconazole undergoes minimal CYP450-mediated metabolism; it inhibits CYP3A4 and several other CYP450 isoforms in vitro and interacts with enzymes involved in glucuronidation, thus leading to certain significant drug–drug interactions.[105,205,222,440] Most important, concurrent therapy with cisapride, pimozide, quinidine, erythromycin, and newer antihistamines results in inhibition of the metabolic pathways of these drugs and potentially serious cardiac arrhythmias and is therefore strictly contraindicated.[207] By similar mechanisms, fluconazole can precipitate phenytoin toxicity,[371] may lead to increased plasma concentrations of cyclosporine and tacrolimus,[318,408] and may potentiate the effects of warfarin, sulfonylurea drugs, rifabutin (in particular, short-acting benzodiazepines and carbamazepine), and nifedipine.[295,318,403,482] Fluconazole also may interfere with the plasma clearance of cyclophosphamide, a widely used anticancer agent that must be metabolized by CYP450 enzymes to produce alkylating species. This interaction may potentially result in a relevant reduction in the therapeutic efficacy of cyclophosphamide.[625] Further potential interactions with anticancer drugs have been observed with busulfan[81] and all-*trans*-retinoic acid.[497]

Clinical Indications. The clinical indications for fluconazole are summarized in Tables 239-2, 239-4, 239-15, and 239-16. Fluconazole is highly effective against superficial infections caused by dermatophytes and *Pityrosporum* spp.,[173,225] and it has excellent activity in the treatment of mucosal candidiasis, including vaginal, oropharyngeal, esophageal, and chronic mucocutaneous candidiasis.[166,219,242,348]

Several controlled studies including both neutropenic and non-neutropenic adult patients indicated that intravenous fluconazole 400 to 800 mg/day is as effective as AmB-D 0.5 to 1 mg/kg/day against candidemia and other forms of invasive candidiasis, but it is better tolerated.* Fluconazole thus can be used for invasive *Candida* infections caused by susceptible organisms in patients who are in stable condition.[415,459] In patients who have received antifungal azoles for prophylaxis, however, breakthrough infections are likely to be caused by fluconazole-resistant *Candida* spp.,[308,355] and alternative agents are recommended. The recommended pediatric dosage range of fluconazole beyond the neonatal period is 6 to 12 mg/kg/day; in view of the faster clearance rate and the absence of population pharmacokinetics, however, 12 mg/kg/day may be the most appropriate dosage.[100,204]

Fluconazole is a useful agent for treatment of invasive *Candida* infections in the neonatal setting. In six published series including 10 or more patients with proved invasive *Candida* infections, treatment with fluconazole at a daily dosage of usually 5 to 6 mg/kg was successful in 83 to 97 percent, and crude mortality ranged from 10 to 33 percent. In none of the 125 patients was fluconazole discontinued because of toxicity.† For infants, population-based pharmacokinetics and Monte Carlo simulation showed that for the treatment of invasive candidiasis, a

*References 76, 308, 320, 385, 490, 501, 537.

*References 12, 16, 415, 435, 457, 459.
†References 64, 72, 148, 149, 163, 263, 575.

dose of at least 12 mg/kg/day in the first 90 days after birth is needed to achieve an AUC/MIC index greater than 50 for *Candida* spp. with MIC less than 8 μg/mL in 90 percent or more of infants at less than 30 weeks' gestation and 80 percent of infants at 30 to 40 weeks' gestation, respectively; according to the model, infants with serum creatinine of 1.3 mg/dL or greater have a slower clearance rate and dose adjustment is indicated if creatinine does not improve within 96 hours.[573,574] A loading dose of 25 mg/kg has been advocated for rapid attainment of target therapeutic drug concentrations.[438]

Fluconazole has been useful in the treatment of focal *Candida* urinary tract infections and uncomplicated funguria, and it has been used successfully in *Candida* peritonitis, endocarditis, osteomyelitis, meningitis, and endophthalmitis.[207,323] Further potential indications for fluconazole beyond the treatment of acute invasive *Candida* infections include consolidation therapy for chronic disseminated candidiasis[11,281] and cryptococcal meningitis.[476,557] High-dose fluconazole is an option for systemic infections caused by the yeast *T. asahii*.[13,203] Fluconazole is the current drug of choice for treatment of coccidioidal meningitis,[178,483] and it has proved effectiveness in nonmeningeal coccidioidal infections.[91,206] Fluconazole appears comparatively less active than itraconazole in the treatment of paracoccidioidomycosis, blastomycosis, histoplasmosis, and sporotrichosis.*

Fluconazole can prevent mucosal candidiasis in patients with HIV infection or cancer,[214,397,443] and it has proved efficacy in preventing invasive *Candida* infections in high-risk patients with acute leukemia or with bone marrow or liver transplants.[196,468,619] Fluconazole, given at 400 mg once daily to adults from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and lower mortality at day 110 after allogeneic bone marrow transplantation,[515] and it also may provide persistent protection against invasive candidiasis and *Candida*-related death. Fluconazole can decrease the frequency of severe, gut-related graft-versus-host disease (GVHD), and it has an independent overall survival benefit of 17 percent at 8 years after the end of treatment.[354] Fluconazole also has been shown to reduce the incidence of *Candida* infections in low-birth-weight infants.† Thus, fluconazole prophylaxis is a valid option for centers with a high frequency (>10%) of invasive *Candida* infections in low-birth-weight infants of less than 1000 g or in the setting of a nosocomial outbreak by a fluconazole-susceptible *Candida* spp. Population pharmacokinetics and Monte Carlo simulation support a dose of 3 or 6 mg/kg twice weekly during the first 42 days of life for early prevention of candidiasis in 23- to 29-week-old infants and a 6-mg/kg dose every 72 hours or 3 mg/kg daily for late prevention.[573,574]

Itraconazole

Itraconazole is a high-molecular-weight, highly lipophilic triazole (see Fig. 239-5). Structurally closely related to ketoconazole, it has a broader spectrum of antifungal activity that includes dermatophytes, *Candida* spp. (*C. krusei* excluded), *C. neoformans*, and *C. gattii*, *Aspergillus* spp., various dematiaceous molds, and the dimorphic fungi. Itraconazole binds more avidly to its fungal target than does ketoconazole, but more weakly to human CYP450, thus leading to comparatively fewer mechanism-associated adverse effects.[198]

Pharmacodynamics. In vitro, itraconazole exerts species- and strain-dependent fungistatic or fungicidal pharmacodynamics. Time-kill experiments in serum-free and serum-containing media demonstrated the concentration-independent, fungistatic activity of itraconazole against *Candida* spp. and *C. neoformans*.[82,83,176,626] However, against *Aspergillus* spp., itraconazole displayed time- and concentration-dependent fungicidal activity with 87 to greater than 97 percent killing within 24 hours of exposure to the drug.[342] Persistent effects have not been reported thus far.

The principal feasibility of a correlation between in vitro susceptibility and outcome was demonstrated in mice with experimental disseminated aspergillosis.[130] Relationships between drug concentrations and antifungal efficacy of itraconazole were assessed in a model of invasive pulmonary aspergillosis in methylprednisolone/cyclosporine-immunosuppressed rabbits. In this model, an inhibitory sigmoid maximum effect model predicted a significant pharmacodynamic relationship (r = .87, p <.001) between itraconazole concentrations in plasma and antifungal efficacy as a function of the burden of *A. fumigatus* in lung tissue.[56]

In patients, however, the main rationale for monitoring plasma levels has been the erratic oral bioavailability of itraconazole, particularly in neutropenic patients. Historically, the target plasma level for itraconazole has been estimated at 0.25 mg/L (high-performance liquid chromatography [HPLC]) at trough, based on the concentration that inhibits 90 percent of a large set of clinical isolates.[70,122] Later, the predictive value of threshold concentrations of prophylactic itraconazole in a large cohort in patients undergoing intensive chemotherapy for acute leukemia was found to be 0.5 mg/L at trough (HPLC) by means of multivariate logistic regression analysis.[188]

In a phase I and II clinical trial of oral cyclodextrin-itraconazole in HIV-infected children with oropharyngeal candidiasis, the relationships between pharmacodynamic parameters and therapeutic response as assessed by standardized scoring of mucosal disease after 14 days of therapy fitted to inhibitory maximum effect pharmacodynamic models. Best fits were observed: AUC, AUC/MIC, C_{max}, and C_{max}/MIC (r = .483 to .595; p <.01).[215]

Pharmacokinetics. Itraconazole is available as capsules and as oral solution in hydroxypropyl-β-cyclodextrin (HP-β-CD). Production of the parenteral solution[5] that also used HP-β-CD as solvent has been discontinued. Absorption of itraconazole from the capsule form depends on a low intragastric pH and is compromised in the fasting state, and it becomes erratic in patients with cancer and granulocytopenia or hypochlorhydria.[105,206,207] Absorption can be somewhat improved when the capsules

*References 135, 177, 228, 280, 282, 413, 414, 604.
†References 60, 232, 273, 283-285, 346, 490, 551.

are taken with food or an acidic beverage.[121,206] The oral solution of itraconazole in HP-β-CD has improved oral bioavailability that is further enhanced in the fasting state; however, this formulation may cause carrier-associated gastrointestinal intolerance.[46,460]

After oral administration, C_{max} is measured within 1 to 4 hours; following once-daily dosing, steady state is achieved after 7 to 14 days.[198,206,230] In adult patients with cancer who were receiving the standard regimen of 2.5 mg/kg of HP-β-CD itraconazole twice daily, mean trough levels were 0.8 mg/L under conditions of steady state[444]; systemic absorption of the carrier was negligible.[122] After administration of the parenteral solution, drug and carrier rapidly dissociated and followed their own disposition; after the recommended regimen of 200 mg twice daily for 2 days followed by 200 mg daily for 5 days, mean trough levels were 0.53 μg/mL. The carrier HP-β-CD was not significantly metabolized, and virtually 100 percent was eliminated from plasma within 24 hours in unchanged form through glomerular filtration.[206]

Itraconazole exhibits dose-dependent pharmacokinetics with nonlinear increases in the AUC with increasing and split dosages.[198,215,444] Itraconazole is highly (95%) protein-bound; only 0.2 percent circulates as free drug.[243] Although concentrations in nonproteinaceous body fluids are negligible, tissue concentrations in many organs, including the brain, may exceed corresponding plasma levels by 2 to 10 times.[121,243]

Itraconazole is metabolized extensively in the liver by numerous pathways to more than 30 metabolites and is excreted in metabolized form into bile and urine. The major metabolite, hydroxyitraconazole, possesses antifungal activity similar to that of itraconazole. It is eliminated more rapidly, but its plasma concentrations at steady state are 1.5 to 2 times higher than those of the parent compound.[122,206,504] The elimination half-life of the compound is 20 to 24 hours after single dosing and 35 to 40 hours under terms of steady state, a finding reflecting saturable excretion mechanisms.[330] The dosage of oral itraconazole does not need to be adjusted in patients with renal insufficiency or dialysis.[372] In patients with severe hepatic insufficiency, the elimination half-life of itraconazole can be prolonged and additional hepatic toxicity or possible drug interactions should be monitored carefully.

Several studies have investigated the pharmacokinetics of the oral HP-β-CD solution of itraconazole in pediatric patients (Table 239-8).[133,215,237,493] In 26 infants and children aged 6 months to 12 years with cancer ($n = 20$) or liver transplantation who received the compound at 5 mg/kg once daily, plasma concentrations were substantially lower than those reported in adult patients with cancer, particularly in children younger than 2 years of age.[133,444] In 16 neutropenic children (1.7 to 14.3 years of age) who received HP-β-CD itraconazole for antifungal prophylaxis in a split dosing regimen of 2.5 mg/kg twice daily, peak and trough levels of itraconazole were substantially higher; nonetheless, a similar trend toward lower plasma concentrations occurred in the group of children 5 years of age and younger.[493] In a cohort of 26 HIV-infected children and adolescents (1.25 to 18 years), HP-β-CD itraconazole was safe and effective for treatment of oropharyngeal candidiasis at dosages of 2.5 mg once per day or 2.5 mg twice daily given for at least 14 days.[215] Many (77%) of the patients were receiving concomitant therapy with protease inhibitors or clarithromycin, drugs that are strong inhibitors of the CYP3A4-dependent metabolism of itraconazole.[440] Peak and trough levels measured after administration of the split-dosage regimen were similar to those observed in patients with cancer who were receiving the same dosage regimen.[493] Of note, population-based pharmacokinetics in pediatric cystic fibrosis and allogeneic bone marrow

transplant patients receiving the oral solution or the capsule formulation as antifungal prophylaxis, however, suggest a starting dose of 5 mg/kg twice daily.[237]

Despite the tremendous interpatient variability that results from both variable absorption and hepatic metabolism, the pharmacokinetic properties of itraconazole in pediatric patients appear not to be fundamentally different from those of adults. A starting dosage of 2.5 mg/kg twice daily can be advocated, based on the available pharmacokinetic data.[133,215,493] Trough levels should be monitored, and dosing should be adjusted to maintain plasma concentrations of the parent itraconazole of greater than 0.5 mg/L by HPLC.[595] Of note, itraconazole is not formally approved for pediatric age groups.

Adverse Effects. Itraconazole usually is well tolerated, with a pattern similar to that of fluconazole and a frequency of adverse effects approximately identical to that seen with fluconazole.[105] In 189 patients treated for systemic fungal infections at dosages of 50 to 400 mg/day for a median of 5 months, the rate of possibly or definitely related adverse effects was 39 percent.[549] Most of the observed reactions were transient and included nausea and vomiting (<10%), hypertriglyceridemia (9%), hypokalemia (6%), elevated hepatic transaminases (5%), rash or pruritus (2%), headaches or dizziness (<2%), and pedal edema (1%). Four percent of patients discontinued itraconazole treatment because of adverse effects. Gastrointestinal intolerance is the dose-limiting toxicity of the oral HP-β-CD formulation. In a comparative study in adult patients with acute leukemia, 46 percent of patients receiving a daily dose of 800 mg stopped treatment early because of severe nausea and vomiting. Crossover to the identical dose of the capsule formulation was well tolerated by all patients; patients receiving 400 mg/day of the solution had no gastrointestinal adverse effects.[187] Only a few cases of more severe hepatic injury or hepatitis have been described.[316] Itraconazole can have negative inotropic effects; because of a low but possible risk for cardiac toxicity, itraconazole should not be administered to patients with ventricular dysfunction.[7]

Cyclodextrin-itraconazole solution was safe and well tolerated for at least 14 days in reported phase I and II pharmacokinetic studies in immunocompromised pediatric patients.[133,215,493] Vomiting (12%), abnormal liver function tests (5%), and abdominal pain (3%) were the most common adverse effects considered definitely or possibly related to HP-β-CD itraconazole solution in an open study in 103 neutropenic pediatric patients with cancer who received the drug at 5 mg/kg daily or 2.5 mg/kg twice daily for antifungal prophylaxis for a median duration of 37 days; 18 percent of patients withdrew from the study because of adverse events.[168] In another report on pediatric patients with cancer who were receiving prophylactic oral itraconazole, adverse effects that led to the cessation of the itraconazole prophylaxis occurred in 11 percent of all 44 courses.[509]

Drug Interactions. In contrast to fluconazole, both the propensity for and the extent of drug–drug interactions are greater.[206,212] Itraconazole is a substrate of CYP3A4, but it also interacts with the heme moiety of CYP3A, thus resulting in noncompetitive inhibition of oxidative metabolism of many CYP3A substrates. An interaction also can result from inhibition of P-glycoprotein–mediated efflux; P-glycoprotein is extensively co-localized and exhibits overlapping substrate specificity with CYP3A.[205,222] Inhibition of hepatic CYP450 enzyme systems may lead to increased and potentially toxic concentrations of coadministered drugs. Most important, the coadministration of cisapride, pimozide, bepridil, mizolastine, terfenadine, astemizole, oral midazolam, quinidine, dofetilide, triazolam, sertindole, eletriptan, nisoldipine, and levacetylmethadol with itraconazole can lead to serious cardiac arrhythmias and is thus strictly contraindicated.[205,249,440] Similarly contraindicated is the coadministration of 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA)-inhibitor cholesterol-lowering agents such as atorvastatin, lovastatin and simvastatin, which are associated with rhabdomyolysis,[205,394] and ergot alkaloids metabolized by CYP3A4, which may result in ergotism. Potentially toxic levels of the coadministered drug also can be reached when itraconazole is given along with phenytoin, carbamazepine, benzodiazepines, cyclosporine, tacrolimus, sirolimus, methylprednisolone, budesonide, digoxin, warfarin, sulfonylurea compounds, ritonavir, indinavir, haloperidol, clarithromycin, verapamil, felodipine, busulfan, and vinca alcaloids.* Increased metabolism of itraconazole resulting in decreased plasma levels can be induced by rifampin, rifabutin, isoniazid, carbamazepine, phenobarbital, and phenytoin.[205,440,548] As a consequence, patients who receive itraconazole along with one of the listed drugs should be followed closely and plasma concentrations of ideally both compounds, as well as hepatic function, should be monitored carefully.

Clinical Indications. The clinical indications for itraconazole are summarized in Tables 239-2 to 239-4, 239-15, and 239-16. Itraconazole is a useful agent for dermatophytic infections, pityriasis versicolor,[3,172,198,227] vaginal candidiasis,[523] and oropharyngeal and esophageal candidiasis.[1,133,215,477] Although the experience with itraconazole in the primary treatment of cryptococcal meningitis is scant, itraconazole has been used with success for long-term treatment of cryptococcal meningitis in patients with HIV infection.[476,557]

Itraconazole may be a second-line option for treatment of invasive *Aspergillus* infections, in particular as maintenance or consolidation therapy in non-neutropenic patients.[132,525] Beyond invasive aspergillosis, itraconazole may be useful in the management of infections by certain dematiaceous molds.[202,507] Itraconazole is a current treatment of choice for lymphocutaneous sporotrichosis[123,280,455] and non–life-threatening, nonmeningeal paracoccidioidomycosis, blastomycosis, and histoplasmosis in non-immunocompromised patients,† as well as induction and maintenance therapy of mild to moderate, nonmeningeal histoplasmosis in HIV-infected patients.[602,603,605] Although earlier uncontrolled clinical trials suggested a somewhat inferior efficacy against nonmeningeal and

meningeal coccidioidomycosis in comparison with fluconazole,[200,546,547] a randomized, double-blind comparative study in patients with progressive, nonmeningeal coccidioidomycosis showed a trend toward slightly greater efficacy when either of the drugs were given at a daily dosage of 400 mg.[179] Nonetheless, amphotericin B remains the treatment of choice for endemic mycoses in most immunocompromised patients and for those with life-threatening infections.[207]

Prophylactic itraconazole may reduce the incidence of proved or suspected invasive fungal infections in patients with hematologic malignancies[364] and those who have undergone HSCT.[352,618] Efficacy in the prevention of invasive aspergillosis is supported by a large meta-analysis,[189] but not by a randomized, comparative trial. Finally, itraconazole was at least as effective as conventional amphotericin B and was superior with respect to its safety profile when it was investigated as empirical antifungal therapy in persistently neutropenic patients with cancer.[71]

Posaconazole

Posaconazole (see Fig. 239-6) is a novel lipophilic antifungal triazole with potent and broad-spectrum activity against opportunistic, endemic, and dermatophytic fungi in vitro. This activity extends to organisms that often are refractory to existing triazoles or amphotericin B or to echinocandins such as *C. glabrata*, *C. krusei*, *A. terreus*, and *Fusarium* spp. Posaconazole also possesses activity against some members of the order Mucorales both in vitro and in vivo, a feature that distinguishes it from all other available azoles.[161,202,479,538]

Pharmacodynamics. Posaconazole is considered fungistatic against *Candida* and fungicidal against *Aspergillus* spp.[202] In time-kill assays, posaconazole showed concentration- and time-dependent fungicidal activity against *A. fumigatus*.[216,343,344] In vivo, in a neutropenic kidney target murine model of *C. albicans* infection and in an inhalational murine model of invasive pulmonary aspergillosis, the AUC/MIC ratio was the parameter predictive of antifungal efficacy.[24,259] In a phase II clinical trial in patients with invasive aspergillosis, higher average plasma concentrations of posaconazole were associated with higher response rates.[589]

Pharmacokinetics. Posaconazole currently is available as oral suspension only and achieves optimal exposure when it is administered in two to four divided doses given with food or a nutritional supplement; common gastrointestinal comorbidities in leukemia- and hematopoietic stem cell transplant patients may negatively affect absorption.[305,306,307] The oral suspension has dose-proportional pharmacokinetics in the 50- and 800-mg dose range, with saturation of absorption occurring at doses higher than 800 mg; after repeat dosing, steady state is achieved after 7 to 10 days with a sixfold to eightfold accumulation of plasma concentrations[114] and marked accumulation within alveolar cells.[106] Posaconazole has a large volume of distribution in the order of 5 L/kg and a prolonged elimination half-life of approximately 20 hours.

Posaconazole is metabolized to a small extent by uridine diphosphate (UDP) glucuronidation; it is not significantly metabolized through the CYP450 enzyme system but is primarily excreted in unchanged form in the feces (Table 239-9).[202,304,601] Posaconazole is a substrate and inhibitor of P-glycoprotein. However, investigation of the relationship between human multidrug resistance gene *(MDR1)* mRNA expression and posaconazole exposure showed no correlation. Thus, the moderate variability in the compound's pharmacokinetics is unlikely to be caused by interindividual differences in P-glycoprotein expression.[115]

Adverse Effects. The overall safety of posaconazole was assessed in two open-label clinical trials of more than 400 patients with invasive fungal infections who received posaconazole suspension 800 mg/day in divided doses. Treatment-related adverse events occurred in 38 percent of patients (164/428); the most common were nausea (8%), vomiting (6%), headache (5%), abdominal pain (4%), and diarrhea (4%). Treatment-related abnormal liver function test results were observed in 3 percent of patients. No clinically significant differences occurred in mean QTc interval change from baseline. Serious adverse events considered possibly or probably related to posaconazole occurred in 35 (8%) patients. The most common severe adverse events were altered drug level, increased hepatic enzymes, nausea, rash, and vomiting (1% each). No significant trends related to age, sex, or race were observed, and no unique treatment-related adverse events were identified in patients during long-term exposure (>6 months) in contrast to those identified during shorter-duration therapy.[421,449] In two large, prospective, randomized comparative clinical trials investigating posaconazole for prevention of invasive fungal infections in high-risk patients with leukemia or HSCT, posaconazole was well tolerated, and the rate of study drug discontinuations in posaconazole-treated patients was not different from that in subjects in the control cohort receiving fluconazole or itraconazole.[111,552]

Drug Interactions. Posaconazole is not significantly metabolized through the CYP450 enzyme system; therefore, CYP450-mediated drug–drug interactions have limited potential to affect posaconazole pharmacokinetics.[304] Posaconazole is a potent inhibitor of cytochrome P3A4, but it has no effect on 1A2, 2C8, 2C9, 2D6, or 2E1 isoenzymes.[601] Concomitant administration of posaconazole with terfenadine, astemizole, cisapride, pimozide, halofantrine, and quinidine can lead to serious cardiac arrhythmias and is thus strictly contraindicated.[486,487] Similarly contraindicated is the coadministration of HMG CoA–inhibitor cholesterol-lowering agents such as atorvastatin, lovastatin, and simvastatin, which are associated with rhabdomyolysis, and ergot alkaloids metabolized by CYP3A4, which may result in ergotism. Potentially toxic levels of the coadministered drug can be reached when posaconazole is given along with phenytoin, carbamazepine, benzodiazepines, cyclosporine, tacrolimus, sirolimus, methylprednisolone, digoxin, warfarin, sulfonylurea compounds, ritonavir, indinavir, atazanavir, haloperidol, clarithromycin, verapamil, nifedipine, diltiazem, nisoldipine, rifabutin, and vinca alkaloids. Because of a relevant decrease in posaconazole concentrations, concomitant use with rifabutin, phenytoin, efavirenz, fosamprenavir, cimetidine, or esomeprazole should be avoided.[80,486,487]

Clinical Efficacy. Posaconazole has been targeted for prevention and treatment of serious infections caused by opportunistic and endemic fungal organisms. Posaconazole has demonstrated strong antifungal efficacy in phase II clinical trials in immunocompromised patients with primary or refractory oropharyngeal and esophageal candidiasis.[514,564] In a randomized, comparative phase III trial, posaconazole 100 mg daily (with day 1 dose 200 mg) was as effective as was fluconazole 100 mg daily (with day 1 dose 200 mg), in the primary treatment of HIV-associated oropharyngeal candidiasis: 155/169 (91.7%) patients receiving posaconazole in contrast to 148/160 (92.5%) of patients receiving fluconazole achieved a complete clinical response (cure). The relapse rate at day 42 was greater in fluconazole recipients than in posaconazole-treated patients (38.2% vs. 31.5%; $p = .038$).[565] Posaconazole 800 mg in divided doses also was investigated as salvage therapy in a large phase II study including 330 patients with invasive fungal infections intolerant to or refractory to standard therapies and a contemporaneous external control of 279 patients.[448] Most patients (86%) were refractory to previous therapy. Successful outcomes at the end of treatment in the posaconazole cohort and in the contemporaneous external control cohort were 42 versus 26 percent in aspergillosis (107 and 86 patients; separately published[589]), 39 versus 50 percent in fusariosis (18 vs. 4 patients), 56 versus 50 percent in zygomycoses (11 vs. 8 patients), 69 versus 43 percent (16 vs. 7 patients) in coccidioidomycosis, 52 versus 53 percent in candidiasis (23 vs. 30 patients), 48 versus 58 percent in cryptococcosis (31 vs. 64 patients), 81 versus 0 percent in chromoblastomycosis (11 vs. 2 patients), and 64 versus 60 percent in other invasive fungal infections (30 vs. 20 patients). In a subset analysis of 39 patients with mostly refractory proved or probable CNS infections, posaconazole proved efficacious against cryptococcal meningitis (success rate in 29 patients [48%]) and against infections caused by opportunistic or endemic molds (5/10 patients [50]).[439,448] These data are in agreement with the compound's extended spectrum of activity in vitro and demonstrate efficacy for treatment of refractory invasive opportunistic and endemic mycoses. A retrospective analysis of the manufacturer's compassionate-use program including 91 patients with proved or probable mucormycosis refractory or intolerant to prior antifungal therapy revealed a 60 percent success rate (complete and partial responses) at 12 weeks after initiation of therapy, thus providing first evidence for the clinical utility of posaconazole as second-line or consolidation therapy of mucormycosis.[554] Posaconazole has also been shown in a randomized, placebo- and active-controlled multicenter trial to be effective against toenail onychomycosis.[156]

Two pivotal preventive randomized phase III studies in high-risk patients with HSCT and GVHD[552] and acute leukemias[111] have been completed. In the first study, patients received either posaconazole 200 mg three times daily or fluconazole 400 mg daily, respectively, with the start of immunosuppression for a total of 16 weeks. Treatment with posaconazole led to a decreased incidence of invasive fungal infections at 16 weeks (5% vs. 9%; $p = .07$), with a statistically significant decrease in invasive *Aspergillus* infections (2% vs. 7%; $p = .006$). Seven days after end of treatment, fewer patients had invasive fungal disease (2% vs. 8%; $p = .004$) and fewer patients had invasive aspergillosis (1% vs. 6%; $p = .001$). No differences in overall mortality rates occurred at 12 weeks.[552] In the second study, patients received posaconazole 200 mg three times daily and either fluconazole 400 mg daily or itraconazole 200 mg twice daily, respectively. Treatment was started with each cycle after a drop of the absolute neutrophil count (ANC) to 500/μL or less for up to 12 weeks. Significantly fewer patients enrolled in the posaconazole arm of the trial developed an invasive fungal infection at day 7 after the end of treatment in contrast to the comparator arm (2% vs. 8%; $p = .01$); most important, treatment with posaconazole resulted in a significant decrease in the rate of invasive aspergillosis (1% vs. 7%; $p = .001$). At day +100 after randomization, the rate of invasive fungal infections was 5 and 11 percent ($p = .01$), respectively, and patients treated with posaconazole had a significantly improved survival probability ($p = .035$).[111] These two important studies demonstrate the preventive efficacy of posaconazole, in particular against invasive *Aspergillus* infections in high-risk patients, and a statistically significant survival benefit in patients with acute myeloblastic leukemia/myelodysplastic syndrome who are undergoing remission induction chemotherapy.

Approval Status and Dosing. In the United States, posaconazole is approved for treatment of oropharyngeal candidiasis, including disease refractory to itraconazole or fluconazole, and for prophylaxis of invasive *Candida* and *Aspergillus* infections in high-risk patients 13 years of age and older with HSCT and GVHD or those with hematologic malignancies and prolonged neutropenia. In the European Union, the compound also is approved for treatment of aspergillosis, fusariosis,

chromoblastomycosis, and coccidioidomycosis refractory to or intolerant of standard therapies in patients 18 years of age and older (see Tables 239-3, 239-4, and 239-16).

The recommended dose for primary treatment of oropharyngeal candidiasis is 100 mg/day (with day 1 dose 100 mg twice daily) and 400 mg twice daily for refractory disease; for prophylaxis of invasive *Candida* and *Aspergillus* infections, the recommended dose is 200 mg three times daily. The dose for salvage treatment is 400 mg twice daily given with food; for patients not tolerating solid food, a dose of 200 mg four times daily is recommended, preferentially together with a nutritional supplement.

Current data indicate no need for adjustments to dosage based on differences in age, gender, race,[488] or renal or hepatic function.[113,116] The pharmacokinetic properties of posaconazole in pediatric patients (<18 years of age) have not been systematically studied. Limited data obtained in 12 pediatric patients 8 years of age and older indicated no fundamental differences in trough plasma concentrations in contrast to that of adults.[307] A twice-daily dosing algorithm based on allometric scaling for posaconazole resulted in adequate exposure in children with chronic granulomatous disease.[599] Successful salvage treatment with posaconazole has been reported in 5/11 and 9/15 pediatric patients with invasive fungal infections, which appears similar to the outcome in the adult population.[67,321] A pediatric development program has been initiated by the manufacturer to define dosages, safety, and tolerance in pediatric patients beyond the neonatal period. In addition, a different oral formulation and an intravenous formulation are in advanced stages of development in the adult population.

Voriconazole

Voriconazole (see Fig. 239-6) is a synthetic antifungal triazole with activity against a wide spectrum of clinically important yeasts and molds, including *Candida* spp., *C. neoformans*, *Aspergillus*, and other hyaline molds, dematiaceous molds, and dimorphic molds, both in vitro and in animal models. A notable exemption is the Mucorales, against which voriconazole is intrinsically inactive.[212,271,272,380]

Pharmacodynamics. Against *Candida* spp. and *C. neoformans*, voriconazole exhibited non–concentration-dependent fungistatic activity; against *A. fumigatus*, voriconazole displayed time-dependent fungicidal activity.[288,342] A concentration-dependent PAFE of 0.2 to 4.1 hours has been observed in the presence of serum against *C. albicans*.[180] In a murine kidney target model of disseminated candidiasis, the AUC/MIC ratio was the pharmacodynamic parameter that correlated best with efficacy. Using 10 *C. albicans* isolates of different voriconazole susceptibilities, the free drug AUC/MIC ratios were similar to all the organisms studied and similar to those observed for other azoles.[25] The AUC/MIC ratio also correlates with antifungal activity in vitro against *A. fumigatus*.[268] Concentration-response relationships of voriconazole in patients were analyzed in a total of 825 subjects from nine previously published clinical trials using logistic regression and Monte Carlo simulation. Whereas logistic regression analysis showed a nonlinear concentration-response relationship with the probability lower at the extremes, Monte Carlo simulation revealed that a trough/MIC ratio of 2:5 was associated with a near-maximal probability of response and that this parameter can be used as the exposure target, on the basis of either an observed MIC or reported MIC_{90} values of the suspected fungal pathogen(s).[545]

Pharmacokinetics. Voriconazole is available in oral and intravenous formulations; oral bioavailability exceeds 90 percent in adults in the fasted state, but it is considerably lower (65%) in children.[577] In adults, the compound has nonlinear pharmacokinetics. Plasma protein binding is 58 percent, and the mean volume of distribution accounts for 2 L/kg. Tissue and CSF levels may exceed those of trough plasma levels severalfold. The plasma half-life is 6 hours, with elimination occurring primarily by oxidative hepatic metabolism to at least eight metabolites that are eliminated through the urine; less than 2 percent of a dose of voriconazole is excreted unchanged in urine. The major isoenzyme involved in voriconazole metabolism is CYP2C19, but CYP2C9 and CYP3A4 also contribute (see Table 239-9). In addition to considerable intrasubject variability, wide between-subject variability exists in the disposition of voriconazole that is in part related to a genetic CYP2C19 polymorphism.[212,377,437,446] Based on this variability, the significant correlations between exposure and effect[545] and significant effects of therapeutic drug monitoring on treatment responses,[418] therapeutic drug monitoring is advocated in patients with life-threatening invasive fungal infections with a target trough concentration of 1 or greater to 2 or greater mg/L of voriconazole.[540,545]

Safety. Voriconazole has an acceptable safety profile. The accrued clinical data indicate that side effects include four distinct clinical categories: transient liver enzyme abnormalities (10% to 20%), skin reactions (<10%), hallucinations or confusion (<10%), and transient, dose-related visual disturbances (altered or enhanced perception of light, blurred vision; 25% to 45%).[212] With regard to the visual disturbances, no morphologic correlation was noted in animal models and the underlying mechanism remains to be elucidated.[272] Drug-related adverse effects requiring the discontinuation of voriconazole were infrequent in comparative clinical trials and ranged from 2 to 13 percent.[9,239,587]

Serious hepatic reactions, including hepatic failure, have been observed during treatment with voriconazole; therefore, evaluation of liver function tests before and during treatment with voriconazole is advised. Azole therapy has been associated with QTc prolongation; for this reason, voriconazole should be administered with caution to patients with proarrhythmic conditions.[212] A possible link among long-term use of voriconazole, immunosuppression, and chronic phototoxicity with aggressive squamous cell carcinoma and melanoma has been reported in adult and pediatric patients.[117,370] As a consequence, the indication for further and prolonged voriconazole treatment in immunocompromised patients

who develop phototoxicity needs to be extremely carefully evaluated. Moreover, fluorosis and periostitis also have been reported during long-term voriconazole use.[600] Voriconazole is teratogenic in animals and may cause fetal harm when it is administered to a pregnant woman.[212]

Drug Interactions. Voriconazole is both substrate and inhibitor of CYP2C19, CYP2C9, and CYP3A4, and, therefore, numerous clinically relevant and potentially hazardous drug–drug interactions must be considered.[205,212] Voriconazole significantly increases exposure to cyclosporin, tacrolimus, benzodiazepines, methadone, fentanyl, alfentanil, Oxycodone, vinca alkaloids, the statins, omeprazole, warfarin, sulfonylurea drugs, phenytoin, protease inhibitors other than indinavir, and nonnucleoside reverse transcriptase inhibitors, thus requiring dosage adjustment or monitoring. Voriconazole exposure is significantly decreased by St. John's wort, phenytoin, ritonavir, efavirenz, rifabutin, carbamazepine, rifampin, and phenobarbital. Concurrent use of the last three enzyme inducers with voriconazole is contraindicated (risk for subtherapeutic levels of voriconazole), as is the concurrent use of terfenadine, astemizole, cisapride, quinidine, pimozide (risk of QTc prolongation resulting from increased exposure to these agents), ergotamine (risk for ergotism resulting from increased exposure), and sirolimus (increased exposure). Dosage adjustments of voriconazole are necessary when the drug must be used concurrently with phenytoin or rifabutin.[80,205,212,272,292]

Clinical Efficacy. Voriconazole has demonstrated excellent clinical efficacy in phase II and III clinical trials in patients with oropharyngeal candidiasis and esophageal candidiasis.[9,235] In salvage studies in patients with fungal infections refractory or intolerant to treatment, complete and partial responses were seen in 43 and 48 percent of patients with invasive aspergillosis,[131,423,584] in 45 to 52 percent of patients with invasive candidiasis,[423] in 30 to 63 percent of patients with scedosporiosis,[423,584] in 45 percent of patients with fusariosis,[423] and in 38 percent of patients with cryptococcosis.[423]

A large, multinational, randomized phase III clinical trial of voriconazole and amphotericin B deoxycholate followed by other licensed antifungal agents for primary therapy of invasive aspergillosis revealed superior outcomes in voriconazole-treated patients.[239] At week 12, successful outcomes were noted in 52.8 percent of the patients in the voriconazole group and in 31.6 percent of those in the amphotericin B group (absolute difference, 21.2 percentage points; 95% confidence interval (CI), 10.4 to 32.9). The survival rate at 12 weeks was 70.8 percent in the voriconazole group and 57.9 percent in the amphotericin B group (hazard ratio, 0.59; 95% CI, 0.40 to 0.88). Voriconazole-treated patients had significantly fewer severe drug-related adverse events. A randomized double-blind clinical trial comparing open-label voriconazole plus blinded anidulafungin or blinded placebo for treatment of proved or probable invasive aspergillosis in patients with hematologic malignancies or allogeneic HSCT has been completed. The preliminary results showed a statistical trend ($p = .07$) favoring the combination therapy with respect to the overall survival at 6 weeks, the primary end point of the study.[356] A randomized comparative study of voriconazole versus amphotericin B deoxycholate followed by fluconazole for treatment of candidemia in non-neutropenic patients showed similar response rates and end-of-treatment and similar survival rates at 3 months.[309] Twelve weeks after the end of treatment, successful outcomes were observed in 41 percent of patients in both treatment groups. Voriconazole cleared blood cultures as quickly as amphotericin B/fluconazole, and significantly fewer serious adverse events and cases of renal toxicity occurred. In a large, international collaborative study of voriconazole versus liposomal amphotericin B for empirical therapy, voriconazole did not meet the prespecified statistical end point for noninferiority in a composite end point but was associated with significantly fewer breakthrough invasive fungal infections, particularly those caused by invasive aspergillosis.[587] Finally, several reports also suggested the potential usefulness of voriconazole for treatment of infections by unusual hyaline and dematiaceous fungi,[423] as well as for treatment of cerebral mold infections.[499]

Voriconazole also has been investigated as primary antifungal prophylaxis.[351,613] A multicenter, randomized, double-blind trial compared voriconazole 200 mg twice daily to fluconazole 400 mg once daily in 600 adult allogeneic HSCT patients. There was no difference in the cumulative rates of proved, probable, and presumptive invasive fungal infections at 6 months (7.3% vs. 11.2% [$p = .12$]); however, a trend was noted toward fewer infections by *Aspergillus* (9% vs. 17%, $p = .09$). Fungal-free survival rates (78% and 75%, respectively) were similar, as were overall survival rates and rates of premature study drug withdrawal.[613] A second study compared voriconazole 200 mg twice daily to itraconazole 200 mg twice daily in 489 allogeneic HSCT recipients. Efficacy was assessed by a composite end point, including survival at 180 days after transplantation and no breakthrough infections and no discontinuation of the study drug for more than 14 days during the first scheduled 100 days. Using this end point, voriconazole was superior to itraconazole, with a 49.1 versus 34.5 percent success rate ($p = .0004$). However, the rate of proved and probable invasive fungal infections was low (3% vs. 6%).[351]

Approval Status and Dosing. Voriconazole is approved in the United States and the European Union for treatment of invasive aspergillosis, fusariosis, and scedosporiosis; treatment of esophageal candidiasis; and primary treatment of candidemia and certain forms of invasive candidiasis in non-neutropenic patients (see Tables 239-2 and 239-3). The recommended intravenous dosages for adults and adolescents (12 to 14 years and ≥50 kg; 15 to 17 years regardless of body weight) are 6 mg/kg twice daily on day 1, followed by 4 mg/kg twice daily. Oral doses in adults are 400 mg twice daily on day 1 (≥40 kg, 200 mg twice daily), followed by 200 mg twice daily (<40 kg, 100 mg twice daily). In patients with renal insufficiency, no adjustment of dosage is needed for the oral formulation; because of the renal clearance of the intravenous carrier, patients with a creatinine clearance of less than 50 mL/min should receive voriconazole by the oral route. In patients with mild-to-moderate hepatic

TABLE 239-10 Simulated Plasma Concentrations of Voriconazole After Multiple Doses of 3 and 4 mg/kg in Pediatric versus Adult Patients

	Value*			
	Pediatric Patients 2-11 yr		Adult Patients	
Parameter	3 mg/kg	4 mg/kg	3 mg/kg	4 mg/kg
AUC_{tau} (ng/hr/mL)	10,670	14,227	13,855	38,605
$C_{average}$ (ng/mL)	889	1,186	1,155	3,217

Modified from Walsh TJ, Karlsson MO, Driscoll T, et al. Pharmacokinetics and safety of intravenous voriconazole in children after single- or multiple-dose administration. *Antimicrob Agents Chemother* 2004;48:2166-72.

*Data are reported as medians following 6 mg/kg every 12 hours on day 1 and maintenance dose 3.

Whereas in pediatric patients, an increase in dosage by a factor of 1.3 leads to proportional increase in the mean average plasma concentration ($C_{average}$) and in the mean area under the concentration versus time curve (AUC_{tau}), adult patients display a 2.8-fold, hyperproportional increase in exposure, indicating nonlinear disposition. As a consequence, pediatric patients given 4 mg/kg do not achieve the same exposure as adults given 4 mg/kg, the dosage that has led to the approval of voriconazole for first-line treatment of invasive aspergillosis.

function abnormalities, half of the daily maintenance dosage is recommended after the initial loading dose. Recommendations for severe liver failure are lacking.[212,272]

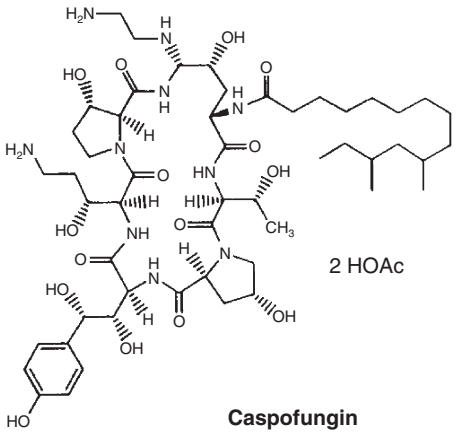
Whereas the disposition of voriconazole in infants younger than 2 years of age has not been systematically investigated,[138] initial pharmacokinetic studies in children 2 to 11 years of age revealed a faster weight-normalized clearance rate than in adults and lower exposure at similar dosages (Table 239-10).[583] This and several subsequent formal pharmacokinetic studies revealed that children need higher exposures relative to adults and that young adolescents 12 to 14 years of age with low body weight (<50 kg) appear to metabolize voriconazole more similarly to children.[147,146,279,577] As a consequence, an intravenous dosage of 8 mg/kg twice daily (with day 1 dose 9 mg/kg twice daily) and an oral dose of the suspension of 9 mg/kg twice daily has been adopted by the European Medicines Agency (EMA) for children 2 years of age to younger than 12 years and 12 to 14 years weighing less than 50 kg and is being further investigated in clinical phase II trials conducted by the manufacturer. Considering the significant relationships between exposure and outcome described earlier, therapeutic drug monitoring should be considered in pediatric patients with life-threatening invasive fungal infections.

Voriconazole has been administered safely and with success to children younger than 12 years of age who had no therapeutic alternative. Of 58 immunocompromised children with proved or probable invasive fungal infection refractory to or intolerant of conventional antifungal therapy, 26 patients (45%) had a complete or partial response and 4 patients (7%) discontinued therapy because of intolerance. A total of 23 patients had voriconazole-related adverse events, most commonly elevations in hepatic transaminases or bilirubin ($n = 8$), skin rash ($n = 8$), abnormal vision ($n = 3$), and photosensitivity reactions ($n = 3$).[584] A large retrospective postmarketing cohort study in 107 immunocompromised pediatric patients who received 252 courses of voriconazole for a median of 65 days (*range*, 1-1001) reported further safety data. Irrespective of causal relationships, increases in hepatic transaminases (53.5%), serum bilirubin (23.6%), and alkaline phosphatase (10.9%), skin eruptions (5.6%), and neurologic adverse events (4.8%) were mostly mild to moderate. Adverse events necessitating discontinuation of voriconazole occurred in 18 courses (7.1%). Treatment success was observed in 16/37 patients with proved, probable, or possible infections, and in 203/215 courses of empirical therapy or prophylaxis.[436] In other pediatric studies providing sufficient information, the rate of drug discontinuations because of adverse events was between 5 and 19 percent. Increases in hepatic transaminases were the most commonly observed adverse advents, followed by skin eruptions, and no consistent correlation between dose or exposure and adverse events have been established.[140] Voriconazole also has been used with success and acceptable tolerance in many patients with cystic fibrosis and allergic bronchopulmonary aspergillosis[245] and as antifungal prophylaxis in patients with hematologic malignancies or allogeneic HSCT.[345,374]

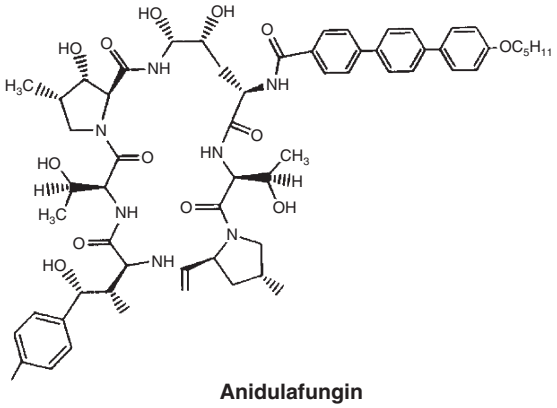
Echinocandin Lipopeptides

The echinocandins are a distinct class of semisynthetic amphiphilic lipopeptides that are composed of a cyclic hexapeptide core linked to a variably configured lipid side chain. The first compound of this class was cilofungin (LY 121019), an echinocandin B derivative with activity limited to *Candida* spp. However, clinical development was abandoned because of concerns regarding toxicity associated with the intravenous polyethylene glycol formulation vehicle.[185,207,475] Since the 1990s, a second generation of semisynthetic echinocandins with extended antifungal spectrum against *Candida* and *Aspergillus* spp., excellent safety profiles, and favorable pharmacokinetic characteristics has been developed: anidulafungin (Eraxis and Ecalta), caspofungin (Cancidas), and micafungin (Mycamine) (Fig. 239-8). With few exceptions, current data indicate that these agents are not fundamentally different with respect to spectrum, pharmacodynamics, pharmacokinetics, safety, and antifungal efficacy.

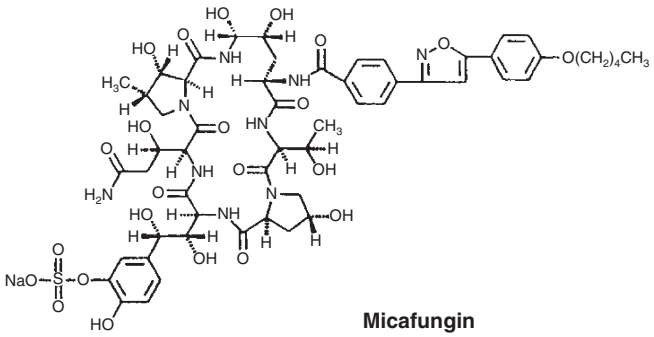
Mechanism of Action. The echinocandins act by noncompetitive inhibition of the synthesis of 1,3-β-D-glucan, a polysaccharide in the cell wall of many pathogenic fungi (Fig. 239-9). Together with chitin, the ropelike glucan fibrils are responsible for the cell wall's strength and shape. They are important in maintaining the osmotic integrity of the fungal cell and play a key role in cell division and cell growth.[126,127,234] The proposed molecular target of the echinocandins, glucan synthase, is a heteromeric enzyme complex composed of at least one large



Caspofungin



Anidulafungin



Micafungin

FIGURE 239-8 ■ Structural formulas of echinocandin lipopeptides: anidulafungin, caspofungin, and micafungin.

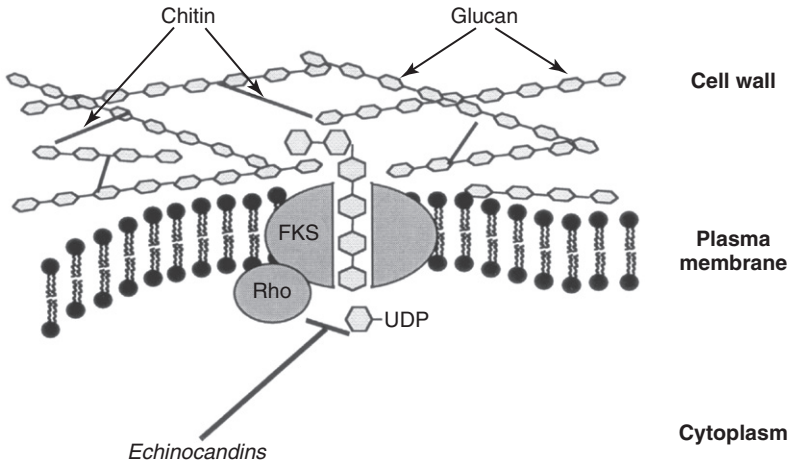


FIGURE 239-9 ■ Schematic of the proposed mechanism of action of echinocandin lipopeptides. Echinocandins inhibit the synthesis of cell wall 1,3-β-glucan at the level of the cell membrane. *FKS* is the proposed catalytic subunit, and *Rho* the proposed regulatory subunit of the glucan synthase complex. (Modified from Kurtz MB, Douglas CM. Lipopeptide inhibitors of fungal glucan synthase. *J Med Vet Mycol* 1997;35:79-86.)

integral membrane protein encoded by the *FKS* gene that binds the substrate (UDP-glucose), and one small regulatory subunit, Rho1p, a guanosine diphosphate (GTP)-binding protein; other, as-yet unidentified, components also may be involved.[310,535] Additional immunomodulatory effects through unmasking of (1→3)-β-D-glucan with proinflammatory host cytokine release have been described and may contribute to in vivo efficacy of the echinocandins.[324]

Antifungal Activity. The echinocandins have potent and broad-spectrum fungicidal in vitro activity against most *Candida* spp., including azole-resistant strains and biofilms, and potent inhibitory activity against *Aspergillus*

spp. Their antifungal efficacy against these organisms in vivo has been demonstrated in various animal models. The current echinocandins have variable activity against dematiaceous and endemic mold and are considered inactive against most Hyalohyphomycetes, Mucorales, *C. neoformans*, and *T. asahii*. All echinocandins have demonstrated preventive and therapeutic activity in animal models of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonitis. Preclinical in vitro and in vivo studies consistently have shown no antagonism between echinocandins and other antifungal agents but have shown indifference, additivity, or synergy when tested against *Aspergillus* spp., *C. albicans*, and non-*albicans Candida* spp.*

Resistance. Whereas the echinocandins show no cross-resistance to amphotericin B, coresistance to both azoles and echinocandins in clinical isolates of *C. glabrata* has been described and is of concern.[431,629] Nevertheless, the frequency of resistance to echinocandins in otherwise susceptible fungal yeast species is low. Reduced echinocandin susceptibility may occur by three mechanisms: adaptive stress responses, which result in elevated cell wall chitin content and paradoxical growth *in vitro* at supraminimum inhibitory concentrations that greatly exceed those achieved in plasma (paradoxical effect); acquired *FKS* mutations, which confer reduced glucan synthase sensitivity, elevated MICs and clinical failure; and intrinsic *FKS* mutations. Intrinsic *FKS* mutations are naturally occurring mutations in the *C. parapsilosis* group and *C. guilliermondii* that confer elevated MIC levels but a lower level of reduced glucan synthase sensitivity in contrast to acquired *FKS* mutations. Of note, some *FKS* mutants have been shown to have significantly reduced fitness and virulence, which may contribute to the low incidence of echinocandin resistance reported in large surveillance studies.[62,310,417,424] New, species-specific clinical breakpoints that consider wild-type MICs, epidemiologic cutoff values, and pharmacokinetic and pharmacodynamic relationships have been proposed that are more sensitive to detect emerging resistance associated with FKS mutations and better able to predict risk for clinical failure.[424,432,466]

Relative to *Candida* spp., much less is currently known about echinocandin resistance among *Aspergillus* spp.; however, clinical breakthrough cases have been reported, and resistance has been confirmed in vivo.[182,258,427]

Pharmacodynamics. The echinocandins demonstrate a species-dependent mode of antifungal activity. Whole-cell in vitro assays reveal fungicidal activity against most *Candida* spp. but not against *Aspergillus* spp.[47,529] Microscopic examination of drug-exposed *A. fumigatus* shows a dose-dependent formation of microcolonies with progressively truncated, swollen hyphal elements that appear to be cell wall deficient but are able to regain their cell walls on subculture in the absence of drug.[143,311,400,454] These observations demonstrate differences in functional target sensitivity that are not fully understood. Time-kill studies in *Candida* spp. demonstrated predominantly concentration- and time-dependent fungicidal activity and rate-of-kill at concentrations greater than the MIC for all three compounds.[159,160,425] In addition, PAFEs between 5 and 12 hours at concentrations above the MIC have been demonstrated.[158,344]

In persistently neutropenic rabbit models, anidulafungin showed highly predictable concentration-effect relationships in experimental disseminated candidiasis; however, no concentration-effect relationships were observed in experimental pulmonary aspergillosis, despite full exploration of the dosage range.[217] Pharmacodynamic studies in murine kidney target models of disseminated candidiasis showed that the AUC/MIC ratio is the pharmacodynamic parameter that predicts efficacy of the echinocandins.[20,21,22,333] In a murine model of invasive pulmonary aspergillosis, the C_{max}/MEC ratio appeared to be the parameter most closely associated with efficacy.[609] Pharmacokinetic and pharmacodynamic correlations of all echinocandins have been explored in patients with esophageal and oropharyngeal candidiasis.[210] Using large datasets from two phase III clinical trials of micafungin for invasive candidiasis, a significant relationship between the AUC/MIC ratio of micafungin and mycologic response was found by population pharmacokinetics and regression analysis; Monte Carlo simulation revealed lower AUC/MIC target for *C. parapsilosis* relative to other *Candida* spp, supporting the concept of species-specific echinocandin susceptibility breakpoints.[22]

Pharmacokinetics. At present, all current echinocandins are available only for intravenous administration. They exhibit dose-proportional plasma pharmacokinetics with a triexponential elimination pattern. Their β half-life is between 10 and 15 hours, thus allowing for once-daily dosing without major accumulation after multiple dosing. All echinocandins are highly (≥95%) protein-bound and distribute into all major organ sites, including the brain; however, concentrations in uninfected CSF are low. Within the lung, anidulafungin and micafungin have been shown to predominantly concentrate in alveolar macrophages. The echinocandins are chemically degraded or metabolized by the liver and slowly excreted into urine and feces; only small fractions (≤2%) of a dose are excreted into urine in unchanged form (Table 239-11).[105,116,118,210,563,581] The current echinocandins are not dialyzable, and no adjustment in dose is required for patients with renal insufficiency or renal failure. Similarly, no adjustment in dose is necessary for patients with mild-to-moderate (all) or severe (anidulafungin, micafungin) hepatic failure. Whether the minor differences in individual pharmacokinetic parameters such as AUC, peak plasma levels, volume of distribution, and clearance of the echinocandins are of clinical significance remains to be elucidated.

Adverse Effects. At current dosages, anidulafungin, caspofungin, and micafungin generally are well tolerated. Fewer than 10 percent of patients enrolled in the various randomized comparative clinical trials discontinued echinocandin therapy because of drug-related adverse events.*

Increased liver transaminases, gastrointestinal symptoms, skin rash, and headache probably or definitely associated with echinocandin treatment have been reported to occur at a frequency of less than 5 percent each. Like other basic polypeptides, the echinocandins have the theoretical potential to cause release of histamine.* Symptoms such as rash, facial swelling, pruritus, sensation of warmth, and anaphylactic reactions have been reported in isolated cases. Because of transient elevations of hepatic transaminases in interaction studies in healthy volunteers,[201] the concomitant use of caspofungin and cyclosporine currently is not recommended; clinical experience, however, indicates that both drugs can be given safely under careful monitoring.[211,353,542]

Drug Interactions. In vitro studies showed that anidulafungin does not significantly inhibit the activities of clinically important human CYP450 isoforms at clinically relevant concentrations and that it is not an inhibitor of P-glycoprotein. Interaction studies demonstrated that no adjustment of dosage of either drug is warranted when anidulafungin is coadministered with cyclosporine, tacrolimus, voriconazole, liposomal amphotericin B, or rifampin.[94]

Caspofungin is not a substrate of P-glycoprotein and is a poor substrate and a weak inhibitor of CYP450 enzymes.[38,623] Clinical studies demonstrated that the pharmacokinetic properties of caspofungin are not altered by itraconazole, amphotericin B, mycophenolate, nelfinavir, or tacrolimus. Caspofungin has no effect on the pharmacokinetics of itraconazole, amphotericin B, or the active metabolite of mycophenolate. Caspofungin can reduce the AUC of tacrolimus by approximately 20 percent, but it has no effect on cyclosporine levels. Inducers of drug clearance or mixed inducer and inhibitors, namely efavirenz, nelfinavir, nevirapine, phenytoin, rifampin, dexamethasone, and carbamazepine, may reduce caspofungin concentrations, and dose adjustment to a daily dose of 70 mg of caspofungin should be considered.[92,201,526]

*References 125, 303, 376, 452, 555, 591.

Micafungin is a weak inhibitor of CYP3A in vitro, but it is neither a P-glycoprotein substrate nor inhibitor in vitro. In clinical studies, micafungin had no effect on mycophenolate mofetil, cyclosporine, tacrolimus, prednisolone, fluconazole, and voriconazole pharmacokinetics, but it increased the AUC of sirolimus, nifedipine, and itraconazole by approximately 20 percent. Patients receiving sirolimus, nifedipine, or itraconazole in combination with micafungin should be monitored for toxicity of these drugs, and sirolimus, nifedipine, and itraconazole dosage should be reduced if necessary. Amphotericin B, mycophenolate mofetil, cyclosporine, tacrolimus, prednisolone, sirolimus, nifedipine, fluconazole, itraconazole, voriconazole, ritonavir, and rifampin were shown to have no effects on the pharmacokinetics of micafungin.[93,221]

Caspofungin

Clinical Efficacy. The clinical efficacy of caspofungin against *Candida* spp. was demonstrated first in phase II and III studies in immunocompromised patients with esophageal candidiasis.[27,570,571] A multicenter, randomized, double-blind phase III clinical trial investigated the efficacy of caspofungin for primary treatment of invasive *Candida* infections in 224 mostly non-neutropenic patients with AmB-D (0.6 to 1 mg/kg) as comparator agent. Among patients receiving at least one dose of the study drug, 73 percent of patients in the caspofungin cohort and 61.7 percent of patients in the AmB-D cohort had therapeutic success at the end of intravenous therapy. Among patients who received five or more doses, the response rates were 80.7 and 64.9 percent, respectively. No difference occurred in relapse or survival, but caspofungin was better tolerated.[376] Further large randomized clinical trials in patients with candidemia and other forms of invasive candidiasis showed similar outcomes of the standard dose of caspofungin relative to 100 and 150 mg daily of micafungin[416] and no general advantage of a high-dose (150 mg/day) caspofungin treatment regimen.[61] In deep-seated invasive candidiasis, including peritonitis, abdominal abscesses, chronic disseminated candidiasis, and arthritis, caspofungin was effective and safe at regular doses and up to 100 mg daily.[109]

A multicenter phase II salvage trial of caspofungin in 83 patients with definite or probable invasive aspergillosis revealed a complete or partial response in 45 percent of patients receiving at least one dose of caspofungin; in patients receiving the drug for more than 7 days, the response rate was 56 percent.[339] Rates of complete or partial responses in subsequent exploratory phase II clinical trials for primary treatment of proved or probable invasive aspergillosis appear to correlate with patients' comorbidities and range from 33[572] and 42 percent[240] to 54 percent.[112] Caspofungin in combination with a triazole or polyene has been shown to be safe and effective in phase II trials and is an option for salvage therapy of invasive aspergillosis.[87,220,336]

In a large, randomized, double-blind clinical trial including 1095 patients, caspofungin was as effective as liposomal amphotericin B for empirical antifungal therapy in persistently febrile granulocytopenic patients, but it was better tolerated. The proportion of patients who survived at least 7 days after therapy was greater in the caspofungin group (92.6% vs. 89.2%).[591] Finally, randomized prospective comparisons suggest that caspofungin may be useful for prophylaxis in high-risk patients with hematologic malignancies.[90,357]

Approval Status and Dosing. Caspofungin is licensed in both the United States and Europe in patients 3 months of age or older with candidemia and certain forms of invasive *Candida* infections, as second-line therapy for invasive aspergillosis, and for empirical antifungal therapy in granulocytopenic patients. In the United States, caspofungin also is approved for treatment of esophageal candidiasis (see Tables 239-2, 239-3, and 239-16).[92] The adult dosage regimen is 50 mg daily, with a single 70-mg loading dose on day 1, administered over 1 hour. No dosage adjustment is required in patients with renal insufficiency and mild hepatic insufficiency. In patients with moderate hepatic insufficiency (Child-Pugh category B), a maintenance dose of 35 mg/day is recommended after the loading dose of 70 mg. No recommendations exist for patients with severe hepatic insufficiency (Child-Pugh category C).[92,201]

In children and adolescents 2 to 17 years of age, the pharmacokinetics and safety of caspofungin were investigated using both a weight-based and a body surface area regimen. Whereas a maintenance dosage of 1 mg/kg/day achieved suboptimal exposure, dosing with 50 mg/m^2/day provided similar or slightly higher exposure relative to adults (Table 239-12).[576] In conjunction with pharmacokinetic data obtained in small children,[391] the dosage of 50 mg/m^2/day (with day 1 dose 70 mg/m^2/day and maximum daily dose of 70 mg) has been selected for pediatric patients between 3 months and 17 years of age. This dosing regimen has been confirmed by a population pharmacokinetic study including 124 pediatric patients 3 months to 17 years enrolled in four clinical trials.[326] In neonates up to 3 months of postnatal age, limited pharmacokinetic data obtained in a small cohort of patients suggest that a dosage of 25 mg/m^2/day results in similar bloodstream exposures as 50 mg/m^2/day in older patients.[402,481] The experience with anidulafungin and micafungin, however, suggests that higher doses will be needed to treat CNS infection.

Caspofungin appears to be well-tolerated in pediatric patients. In the previously mentioned phase I and II dose-finding studies, none of the patients developed a serious drug-related adverse event or discontinued because of toxicity.[391,481,576] In a phase III estimation trial with safety as the primary objective, 82 patients between the ages of 2 and 17 years with persistent fever and neutropenia were randomly assigned to receive caspofungin or liposomal amphotericin B 3 mg/kg daily in a 2:1 ratio. Rates of drug-related adverse events were similar (clinical 48.2% vs. 46.2%; laboratory 10.7% vs. 19.2%); serious drug-related adverse events occurred in 1.8 percent of caspofungin-treated patients and in 11.5 percent of amphotericin B-treated patients. Overall success rates were not different.[337] A prospective phase II trial in 49 patients with invasive *Candida* or *Aspergillus* infections revealed no serious drug-related adverse events and an overall response rate of 73 percent.[628] In the combined analysis of caspofungin safety in all five clinical registration trials involving 171 pediatric patients 1 week to 17 years of age, the most common drug-related adverse

TABLE 239-12 **Single-Dose Caspofungin Pharmacokinetics in Pediatric Versus Adult Patients***

	Children (2-11 yr)			
Dosage	**1 mg/kg**	**50 mg/m^2**	**Adolescents (12-17 yr) 50 mg/m^2**	**Adults 50 mg**
$AUC_{0\text{-}24\ hr}$ (μg/hr/mL)	41.5	96.4	77.6	70.6
C1 (μg/mL)	6.59	13.9	7.67	7.67
C24 (μg/mL)	0.45	1.09	1.35	1.35
$t_{1/2}\beta$ (hr)	7.2	7.6	11.7	11.7
Cl (mL/min/m^2)	8.57	7.78	6.07	6.07

Modified from Walsh TJ, Adamson PC, Seibel NL, et al. Pharmacokinetics, safety, and tolerability of caspofungin in children and adolescents. *Antimicrob Agents Chemother* 2005;49:4536-45.

*Least square means are reported for AUC, C1 (peak plasma concentration [C_{max}]), and C24 (minimum plasma concentration [C_{min}]), and harmonic means for $t_{1/2}\beta$. Data were obtained in groups of 6 to 10. Data in pediatric patients were compared with those obtained in 32 adult patients with mucosal candidiasis. In comparison with adult values, a 1-mg/kg dosage does not achieve the target trough concentration of caspofungin of 1 μg/mL and leads to a lower exposure as measured by the $AUC_{0\text{-}24\ hr}$; the dosage regimen of 50 mg/m^2 leads to similar or slightly higher trough concentrations and similar or slightly higher exposure ($AUC_{0\text{-}24\ hr}$).

AUC, Area under the concentration versus time curve from 0 to 24 hours; *Cl,* clearance; $t_{1/2}\beta$, elimination half-life.

events were fever (11.7%), increased alanine aminotransferase level (6.5%), and rash (4.7%); few events were serious (0.6%) or required treatment discontinuation (1.2%).[627] Favorable safety experiences also have been reported in immunocompromised pediatric patients who received the compound for various indications, mostly in combination with other antifungal agents,[141,171,211] and in neonates with refractory invasive candidiasis.[387,401,402]

Anidulafungin

Clinical Efficacy. The clinical efficacy of anidulafungin against *Candida* spp. was demonstrated in phase II or III studies in immunocompromised patients with esophageal candidiasis and candidemia. Anidulafungin had efficacy equivalent to that of fluconazole in esophageal candidiasis in a randomized, double-blind, international multicenter study; success was documented in 242/249 evaluable anidulafungin-treated patients (97.2%) and in 252/255 fluconazole-treated patients (98.8%). Adverse events leading to discontinuation were reported in 29 anidulafungin-treated patients (10%) versus 23 fluconazole-treated patients (8%).[302] In a dose-ranging study in 123 patients with invasive candidiasis randomized to anidulafungin 50, 75, or 100 mg once daily, success rates at end of therapy were 84, 90, and 89 percent, respectively.[303] A subsequent randomized, double-blind phase III noninferiority trial compared anidulafungin 100 mg once daily with fluconazole 400 mg once daily in a total of 245 mostly non-neutropenic patients with invasive candidiasis.[452] More patients receiving anidulafungin had clinical and microbiologic success at the end of intravenous therapy (75.6% vs. 60.2%); similar superiority was found at the 2- and 6-week follow-up after the end of all therapy (64.6% vs. 49.2% and 55.9% vs. 44.1%, respectively). The rate of death from all causes was 31 percent in the fluconazole group and 23 percent in the anidulafungin group (p = .13). Taken together, anidulafungin was shown to be noninferior to fluconazole on treatment of invasive candidiasis. Very recently, a randomized double-blind clinical trial comparing open-label voriconazole plus blinded anidulafungin or blinded placebo for treatment of proved or probable invasive aspergillosis in patients with hematologic malignancies or allogeneic HSCT has been completed. The results showed a statistical trend (p = .07) favoring the combination therapy with respect to the overall survival at 6 weeks, the primary end point of the study.[356] Because the full report has not been published and the data have not been reviewed by regulatory authorities, the clinical implications of this study are not clear at present.

Approval Status and Dosing. Anidulafungin is licensed in both the United States and Europe for patients 18 years of age or older for candidemia and certain forms of invasive *Candida* infections in non-neutropenic patients. In the United States, the compound is also licensed for esophageal candidiasis (see Table 239-2).[94] The recommended dose regimen consists of 100 mg (with day 1 dose 200 mg) for invasive candidiasis and 50 mg daily (with day 1 dose 100 mg), for esophageal candidiasis, administered at a rate of 1.1 mg/min or higher. No dosage adjustment is needed in patients with renal impairment, patients undergoing hemodialysis, and patients with hepatic impairment (Child-Pugh classes A, B, and C).[94,462]

A pediatric phase I and II multicenter study of the pharmacokinetics and safety of anidulafungin has been completed in 19 granulocytopenic children with cancer. Patients were divided into two age cohorts (2 to 11 and 12 to 17 years) and were enrolled into sequential groups to receive 0.75 or 1.5 mg/kg/day[51] (Table 239-13). No drug-related serious adverse events were recorded. Pharmacokinetic parameters were similar across age groups and dosage cohorts and similar relative to adult patients.

Data from Benjamin DK Jr, Driscoll T, Seibel NL, et al. Safety and pharmacokinetics of intravenous anidulafungin in children with neutropenia at high risk for invasive fungal infections. *Antimicrob Agents Chemother* 2006;50:632-8; and Vasquez JA, Sobel JD: Anidulafungin: a novel echinocandin. *Clin Infect Dis* 2006;43:215-22.

*Pharmacokinetic parameters are expressed as mean values. Data were obtained in groups of six pediatric patients with compromised immunity and neutropenia per age group and dosage level and were compared with those obtained in 26 adult healthy volunteers.

†$t_{1/2}\gamma$.

AUC, Area under the concentration versus time curve from 0 to 24 hours; *Cl,* clearance; C_{max}, peak plasma concentration; *N/A,* not available; $t_{1/2}\beta$, elimination half-life; Vd_{ss}, volume of distribution at steady state.

Following single and multiple daily doses of 0.75 mg/kg and 1.5 mg/kg, plasma concentration data corresponded to those in adults following a daily 50 and 100 mg dose, respectively.[51] In infants and neonates at risk for invasive candidiasis receiving 1.5 mg/kg/day anidulafungin after a single loading dose of 3 mg/kg, drug exposure levels after multiple doses were similar between neonates and infants and similar to those in children receiving similar weight-based dosing and in adult patients receiving 100 mg/day. No drug-related serious adverse events were observed.[104] Bridging studies from laboratory animals, however, indicate that a regimen of 3 mg/kg, followed by 1.5 mg/kg/day, is suboptimal for treatment of *Candida* meningoencephalitis and that higher dosages will be required to treat this condition.[594] Although further data are not available at this point, the pediatric development program of the compound is in advanced stages.

Micafungin

Clinical Efficacy. Micafungin was studied in open-label dose-ranging trials of endoscopically proved esophageal candidiasis in patients with HIV infection.[426,527] A double-blind comparative study investigating 50, 100, and 150 mg/day versus fluconazole 200 mg/day for HIV-associated esophageal candidiasis showed similar endoscopic cure rates and safety profiles for micafungin at doses of 100 and 150 mg/day and fluconazole.[125] A further randomized, double-blind comparative trial in 523 patients 16 years of age and older with esophageal candidiasis investigated micafungin 150 mg/day versus fluconazole 200 mg/day.[124] For the primary end point of endoscopic cure, treatment difference was 0.3 percent (micafungin, 87.7%; fluconazole, 88.0%). A large randomized, double-blind noninferiority trial compared micafungin 100 mg once daily and liposomal amphotericin B 3 mg/kg once daily for first-line therapy of candidemia and other forms of invasive candidiasis in a total of 531 adult patients. The overall success rate in both treatment arms was similar (89.6% vs. 89.5%). No differences in survival were noted. Fewer severe treatment-related adverse events and adverse events that led to treatment discontinuation were observed in the micafungin arm.[312,471] In a second large, phase III, randomized clinical trial of a total of 595 patients with candidemia and other forms of invasive candidiasis, micafungin at 100 mg/day, micafungin at 150 mg/day, and caspofungin at 50 mg/day (with day 1 dose 70 mg) were equivalent in terms of efficacy, adverse events, and mortality.[151,416] A multinational, noncomparative open-label trial investigated micafungin for proved and probable invasive aspergillosis alone or in combination with another antifungal agent. A favorable response rate at the end of therapy was seen in 35.6 percent (80/225) of patients. Of those treated with only micafungin, favorable responses were seen in 6/12 (50%) of the primary and 9/22 (40.9%) of the salvage therapy group, with corresponding numbers in the combination treatment groups of 5/17 (29.4%) and 60/174 (34.5%) of the primary and salvage treatment groups, respectively.[128] Finally, micafungin 50 mg/day (<50 kg, 1 mg/kg) versus fluconazole 400 mg/day (<50 kg, 8 mg/kg) was investigated for prevention of invasive fungal infections in 882 patients undergoing HSCT. Prophylaxis was given from the start of the conditioning regimen until 5 days after engraftment. The overall success rate was significantly higher for patients randomized to receive micafungin (80.0% vs. 73.5%; $p = .03$). Drug-related adverse events were comparable.[555]

Approval Status and Dosing. In the United States, micafungin is licensed in adults for prevention of *Candida* infections in patients undergoing HSCT, for treatment of candidemia and defined forms of invasive candidiasis, and for treatment of esophageal candidiasis (see Table 239-2). In Europe, the compound is licensed for use in neonates, children, and adults for treatment of invasive candidiasis and as prophylaxis of *Candida* infections in patients with allogeneic HSCT and those with prolonged neutropenia; it is also licensed for treatment of esophageal candidiasis in individuals 16 years of age and older. The recommended dosage is 100 mg/day for invasive candidiasis (≤40 kg, 2 mg/kg), 150 mg/day for esophageal candidiasis (≤40 kg, 3 mg/kg), and 50 mg/day (≤40 kg, 1 mg/kg) for the preventive indication. Renal dysfunction, dialysis, or hepatic dysfunction does not alter the pharmacokinetics of micafungin.[93,233]

The pharmacokinetics and safety of micafungin have been studied in 70 febrile granulocytopenic children 2 to 17 years of age. Micafungin was well tolerated at dosages of 0.5 to 3 mg/kg/day; pharmacokinetics were linear and similar to those observed in adults (Table 239-14).[503] Population-based pharmacokinetic modeling of the data revealed that clearance in smaller children was higher than predicted on the basis of weight alone, requiring a relative dosage increase to ensure exposure comparable to that in older children; however, dosages of 2 mg/kg and 4 mg/kg in the children achieved exposures at least similar to 100 mg and 200 mg, respectively, in adults.[251] Of note, in the setting of prophylaxis, alternate dosing of micafungin (3 mg/kg) every other day provides drug exposure similar to standard dosing of 1 mg/kg given daily, and may provide an alternative for antifungal prophylaxis in high-risk patients.[361]

The pharmacokinetics in neonates were explored in a phase I single-dose, multicenter, open-label, sequential-dose trial of micafungin 0.75 mg/kg, 1.5 mg/kg, and 3 mg/kg in 18 premature infants weighing more than 1000 g. On average, half-life was shorter and clearance more rapid in contrast to older children and adults.[241] Population pharmacokinetics modeling of the neonatal pharmacokinetics data and Monte Carlo simulation suggest that a larger neonatal dose is required to produce drug exposure comparable to those predicted on the basis of weight in children and adults; additional population pharmokinetics based on open-label pharmokinetics studies with doses up to 15 mg/kg/day support a target dose of 10 mg/kg for neonates, particularly in view of the substantial risk for secondary brain involvement.[52,250,252,516] Although the treatment results in the pivotal candidemia study showed no signal for decreased efficacy at dosages between 2 and 4 mg/kg in this population,[447] we recommend a dose of at least 4 mg/kg in neonates with invasive candidiasis and a dose of 10 mg/kg in the case of CNS involvement.

TABLE 239-14 **Single-Dose Micafungin Pharmacokinetics in Pediatric Versus Adult Patients***

	Pediatric Patients (2-17 yr)			*Adults*

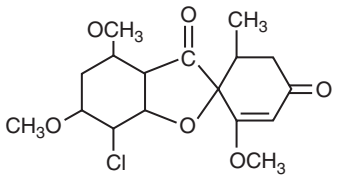
A noncomparative phase II study investigated the activity of micafungin alone or in combination with other agents in 58 pediatric patients with mostly refractory invasive aspergillosis. Most patients (n = 56) received micafungin in combination with another agent, primarily liposomal amphotericin B (n = 47). The mean daily dose was 2.0 ± 1.2 mg/kg/day, and the mean duration of dosing was 67 ± 85 days. Overall response was 26/58 (45%). Thirteen patients (22%) discontinued micafungin, primarily because of a progression of underlying disease or invasive aspergillosis.[167] The comparative safety of micafungin was investigated in the pediatric subpopulation of a double-blind, phase III trial in patients with invasive candidiasis or candidemia. Patients were randomized to receive intravenous micafungin 2 mg/kg/day or liposomal amphotericin B 3 mg/kg/day for a minimum of 14 days. There was no difference in the success rates (69.2% vs. 74.1%). The incidence of serious adverse events (3.8% vs. 9.3%) and the rate of patients discontinuing therapy because of an adverse event (3.8% vs. 16.7%) were lower in patients treated with micafungin.[447] In a pooled analysis of adverse events data from six clinical trials that included close to 300 patients, 26.7 percent of patients had a treatment-related adverse event and 2.4 percent had a treatment-related adverse event that led to treatment discontinuation. No trends were seen with respect to dose or duration of treatment, and the types and rates of events were similar to those observed in adults.[28,31]

In Europe, the Summary of Product Characteristics for micafungin recommends careful monitoring of liver function and early discontinuation in the presence of significant and persistent elevation of alanine aminotransferase and aspartate aminotransferase values. It also recommends that micafungin treatment be conducted on a careful risk-benefit assessment, particularly in patients with liver diseases or concomitant hepatotoxic-genotoxic therapies.[35] This recommendation is based on preclinical data from a high-dose, long-term exposure model in rats treated with micafungin for either 3 or 6 months (equivalent to 12.5% or 25% of the total life span of the rat, respectively). The observed development of foci of altered hepatocytes and liver tumors in this species was dependent on both dose and duration of micafungin treatment. The human relevance of this finding is presently not known.



Griseofulvin

FIGURE 239-10 ■ Structural formula of griseofulvin.

AGENTS FOR SYSTEMIC TREATMENT OF MYCOSES OF THE SKIN AND ITS APPENDAGES

Griseofulvin

Griseofulvin (Fig. 239-10) was isolated originally in 1939 as a natural product of *Penicillium griseofulvum*.[410] However, only in the late 1950s was it reported to be effective as an antifungal agent.[184] Griseofulvin has been used since extensively for the systemic treatment of superficial dermatophyte infections in both adults and children.

Mechanism of Action. Griseofulvin interferes with fungal microtubule formation. It disrupts the cell's mitotic spindle formation and thus arrests the metaphase of cell division.[223] Several additional mechanisms of action have been proposed, including inhibition of nucleic acid synthesis, interference with the synthesis of cell wall chitin, and anti-inflammatory properties.[225] Griseofulvin is deposited in keratin precursor cells and produces an unfavorable environment for fungal invasion; infected skin, hair, and nails are replaced with tissue not infected by the dermatophyte.

Antifungal Activity. As evident from its mechanism of action, griseofulvin is a fungistatic compound. It is active against *Trichophyton*, *Microsporon*, and *Epidermophyton* spp. The drug has no activity against yeastlike organisms such as *Candida* spp., *Pityrosporum* spp., and *C. neoformans*. It also is inactive against opportunistic hyaline and dematiaceous molds and the dimorphic (endemic) molds.[164,172]

Pharmacokinetics. Griseofulvin is commercially available for oral administration only as griseofulvin microcrystalline and griseofulvin ultramicrocrystalline. Microcrystalline griseofulvin contains predominantly particles in the order of 4 μm in diameter, and ultramicrocrystalline griseofulvin contains predominantly particles of less than 1 μm in diameter. Griseofulvin is weakly water soluble and poorly absorbed from the gastrointestinal tract. In contrast to nonmicrocrystalline drug preparations, microcrystalline and ultramicrocrystalline formulations display enhanced absorption, particularly when polyethylene glycol is used as dispersion carrier in the ultramicrocrystalline formulations. Oral bioavailability of the microcrystalline formulation is variable and ranges from 25 to 70 percent; ultramicrocrystalline griseofulvin, in contrast, is almost completely absorbed.[66,225]

After oral administration, C_{max} occurs approximately 4 hours after dosing. Griseofulvin distributes to keratin precursor cells and is concentrated in skin, hair, nails, liver, adipose tissue, and skeletal muscles. In skin, over time, a concentration gradient is established, with the highest concentrations found in the outermost stratum corneum.[157,506] Non–protein-bound drug is carried in the extracellular fluid, in sweat, and through transepidermal fluid loss; in addition, reversible protein binding and high lipid solubility cause griseofulvin to partition into the stratum corneum, where its concentrations exceed that of serum. Within 48 to 72 hours after discontinuation of the drug, plasma concentrations of griseofulvin are markedly reduced, and the compound no longer is detectable in the stratum corneum.[66,225]

Griseofulvin is oxidatively demethylated and conjugated with glucuronic acid primarily in the liver; its major metabolite, 6-desmethylgriseofulvin, is microbiologically inactive.[327] The elimination of the compound from plasma is bi-exponential, with a terminal elimination half-life of 9 to 21 hours.[469] Approximately one third of a single dose of microcrystalline griseofulvin is excreted in feces, and 50 percent is excreted in urine within 5 days. In urine, the drug is excreted mainly as free and glucuronized 6-desmethylgriseofulvin. Unchanged drug in the urine accounts for less than 1 percent of the dose.[327,328]

Separate pharmacokinetic data for pediatric patients have not been published; however, the compound is approved for children older than 2 years of age. The recommended pediatric dosage of microcrystalline griseofulvin is 10 to 20 mg/kg/day, with a maximum of 1 g, administered in two divided doses; the recommended pediatric dosage of ultramicrocrystalline griseofulvin is 5 to 10 mg/kg/day (maximum, 750 mg), also given in two divided doses.[154,173]

Adverse Effects. Griseofulvin has an acceptable safety profile. More common adverse effects include headaches and a variety of gastrointestinal symptoms. Griseofulvin can cause photosensitivity and exacerbate lupus and porphyria. Cases of erythema multiforme–like reactions, toxic epidermal necrolysis, and a reaction resembling serum sickness have been reported. Proteinuria, nephrosis, hepatotoxicity, leukopenia, menstrual irregularities, and mental confusion have been reported rarely in association with griseofulvin therapy. Griseofulvin has been noted to produce estrogen-like effects in children and reversible diminution of hearing.[66,172,225] Griseofulvin is contraindicated in patients with porphyria or hepatocellular failure. The compound has been shown to be teratogenic in animals and should not be administered to pregnant women. Griseofulvin also has mutagenic and carcinogenic potential; the significance of these observations for humans, however, is unclear.[172,173]

Drug Interactions. Griseofulvin has been noted to enhance the clearance of oral contraceptives, cyclosporine, theophylline, aspirin, and warfarin. Concurrent use of phenobarbital may lead to decreased levels of griseofulvin. Finally, concurrent ingestion of alcohol may lead to a disulfiram-like reaction.[172,173]

Indications. Griseofulvin remains an option for the treatment of tinea capitis, particularly when caused by *M. canis*, and refractory tinea corporis (Table 239-15).[153,165, 502] For tinea capitis, 6 to 8 weeks of treatment usually are required.[154,257] The usual duration of therapy for refractory tinea corporis is 4 weeks.[154,174] Nail infections, which are increasingly observed in the pediatric population,[186] usually fail to respond to therapy with griseofulvin and are better treated with itraconazole or terbinafine. Because griseofulvin is not effective against other fungal infections (Table 239-16), the infecting organism always should be identified as a dermatophyte before therapy is initiated. In vitro resistance of dermatophytes to griseofulvin has been reported and may be the cause of therapeutic failure.[33]

Terbinafine

The allylamine terbinafine (Fig. 239-11) is a synthetic antifungal agent that is useful for topical and systemic (oral) treatment of superficial infections of the skin and its appendages by dermatophytes and yeasts, as well as possibly for treatment of cutaneous sporotrichosis.

TABLE 239-15 Options for Medical Management of Superficial Infections by Dermatophytes

Fungal Disease	Management*
Tinea capitis	Griseofulvin for a total of 6-8 wk
	Fluconazole, itraconazole for 4 wk
	Terbinafine for 4 wk
Tinea unguium	Itraconazole for 3-4 mo
	Terbinafine for 6 wk (fingernail) or 12 wk (toenail)
Tinea corporis, facialis, pedis	Topical antifungal azoles:
	Miconazole, clotrimazole, econazole, ketoconazole, sulconazole, oxiconazole bid for 2-4 wk
	Topical allyl/benzylamines, thiocarbamates:
	Terbinafine, naftifine, butenafine, tolnaftate daily to twice daily for 2-4 wk
	Other topical agents:
	Ciclopirox olamine bid for 2-4 wk
	Refractory infections/immunocompromised patients:
	Griseofulvin for 2-4 wk
	Fluconazole for 2-4 wk
	Itraconazole for 2-4 wk
	Terbinafine for 2-4 wk

TABLE 239-16 Options for Medical Management of Superficial Infections by Yeasts

Fungal Disease	Management*
Candida dermatitis	Topical antifungal azoles:
Tinea versicolor	Miconazole, sulconazole, econazole, oxiconazole, clotrimazole bid for 2-4 wk
	Topical polyenes:
	Amphotericin B or nystatin bid/qid for 2-4 wk
	Other topical agents:
	Ciclopirox olamine bid for 2-4 wk
	Refractory infections/immunocompromised patients:
	Fluconazole for 2-4 wk
	Itraconazole for 2-4 wk
Oropharyngeal candidiasis	Topical polyenes:
	Nystatin or amphotericin B four times daily for ≥2 wk
	Topical antifungal azoles:
	Clotrimazole lozenges five times daily for ≥2 wk
	Refractory infections/immunocompromised patients:
	Fluconazole for ≥2 wk
	Itraconazole for ≥2 wk
	Voriconazole
	Posaconazole
	Amphotericin B deoxycholate
	Echinocandin lipopeptides
Vulvovaginal candidiasis	Topical antifungal azoles:
	Miconazole, clotrimazole, butoconazole, terconazole, tioconazole qhs for ≥7 days
	Topical polyenes:
	Nystatin qhs for 14 days
	Systemic antifungal azoles:
	Fluconazole 150 mg PO × 1day/50 mg PO × 3days
	Refractory infections/immunocompromised patients:
	Fluconazole for ≥2 wk
	Itraconazole for ≥2 wk
	Amphotericin B deoxycholate

Terbinafine

FIGURE 239-11 ■ Structural formula of terbinafine.

Terbinafine acts by inhibiting the biosynthesis of fungal ergosterol at the level of squalene epoxidase (see Fig. 239-8), thus leading to depletion of ergosterol and accumulation of toxic squalenes in the fungal cell membrane.[41]

Antifungal Activity. Terbinafine has exceptionally potent and fungicidal in vitro activity against dermatophytes.[165] It also is highly active against *Aspergillus* spp., certain hyalohyphomycetes, dematiaceous and dimorphic fungi, and *P. jiroveci*. Its in vitro activity against yeasts appears more variable.[181,207,270,474] Comparative studies have indicated that terbinafine may be more active against *Aspergillus* spp. than itraconazole[505] or amphotericin B,[494] more active than itraconazole against *S. schenkii*,[293] and less or comparably active than the azoles against yeasts.[505] Synergy with triazoles against *C. albicans*,[169,598] *C. glabrata*,[44] *C. neoformans*,[169] *A. fumigatus*,[72,381] non-*Aspergillus* hyalohyphomycetes,[362,363,406,474] and Mucorales[195] has been reported. Although more variable, synergy with amphotericin B also has been demonstrated for filamentous and yeastlike fungi.[474] Terbinafine resistance in clinical dermatophyte isolates is a rare occurrence; only two cases have been documented in which the resistance mechanism was identified as a single amino acid substitution in squalene epoxidase.[407]

Pharmacokinetics. The pharmacokinetic properties of terbinafine in adults are well characterized.[41] Independent of food, oral bioavailability is 70 to 80 percent. Over the adult dosage range of 125 to 750 mg once daily, terbinafine displays linear plasma pharmacokinetics. C_{max} of 0.5 to 2.7 g/L is measured within 2 hours,[267,298,299] and steady state is reached after 10 to 14 days after only twofold accumulation.[41] As a lipophilic drug, terbinafine is strongly bound to plasma proteins. The compound is distributed extensively to tissues and accumulates throughout adipose tissues, dermis, epidermis, and nail. It exhibits a triphasic distribution pattern in plasma, with a terminal half-life up to 3 weeks; microbiologically active concentrations can be measured in plasma for weeks to months after the last dose, a finding consistent with a slow redistribution from peripheral tissue and adipose tissue sites.[41,299,390] Terbinafine undergoes extensive and complex hepatic biotransformation that involves at least seven CYP450 enzymes.[569] Fifteen metabolites have been identified, mainly in urine; none has been shown to be mycologically active.[299] Studies employing radiolabeled drug demonstrated that urinary excretion accounts for more than 70 percent and fecal elimination for 10 percent of radioactivity; the extent of enterohepatic recycling is unknown.[260,262] As a consequence of the compound's extensive hepatic metabolism and urinary excretion, caution is warranted in treating patients with severe hepatic and renal impairment (creatinine clearance ≤50 mL/min).[41]

The pharmacokinetic properties of terbinafine and five known major metabolites in plasma and urine were investigated carefully after single and repeated oral administration of 125 mg/day to 12 pediatric patients for up to 56 days (mean age, 8 years; age range, 5 to 11 years; weight range, 17 to 34 kg) (Table 239-17). No differences were found regarding the metabolism of terbinafine in contrast to that in healthy adults. Steady state was reached at least on day 21, and no further accumulation occurred between days 21 and 56.[260,393] Comparison of the kinetic parameters of terbinafine after single administration of 125 mg showed comparable C_{max} and T_{max} (time until occurrence of C_{max}) values and a 40 percent higher AUC; when dose was calculated as milligrams per kilogram or milligrams per square meter, children showed a lower AUC (range, 29% to 45%) in contrast to that in adults, a finding indicating a higher, weight-normalized volume of distribution into lipophilic tissue. Children had shorter β-phase elimination half-lives, but the γ-phase, terminal half-life determined after multiple dosing during washout was similar to that in adults. Thus, in children weighing 17 to 34 kg, a dose of 125 mg terbinafine yields pharmacokinetic properties similar to those in adults without drug accumulation, and use of a calculation of milligrams per kilogram or milligrams per square meter would lead to lower drug levels than those recorded in adults.[4,260,274,393] Exploration of lower doses (62.5 mg/day) in eight children weighing 19 to 35 kg revealed an approximate reduction in trough level of 50 percent, a finding indicating linearity of plasma pharmacokinetics in children.[274] Based on the experience with dosages of 10 mg/kg and less in adults and the described pharmacokinetic profile of the compound in children, a dose of 250 mg/day has been proposed for children weighing more than 40 kg, a dose of 125 mg/day for children weighing 20 to 40 kg, and 62.5 mg/day for children weighing less than 20 kg.[274]

Adverse Effects. In adults, terbinafine usually is well tolerated at doses of up to 500 mg/day, and it has a relatively low incidence of adverse effects. The primary adverse effects associated with terbinafine include gastrointestinal upsets, headache, and skin reactions in 2 to 7 percent of patients. Terbinafine can cause hepatitis and liver failure. Potentially severe hepatotoxicity is estimated to occur in 1/120,00 patients, and asymptomatic rises in liver enzyme activities are likely to occur at a frequency of 1/200. Although hepatotoxicity may occur in patients with or without chronic or active liver disease, the drug should not be administered in patients with an underlying liver problem and liver function tests results should be obtained before terbinafine is prescribed. Less common

TABLE 239-17 **Pharmacokinetic Parameters of Terbinafine in Children After a Single Dose of 125 mg Compared with Similar Parameters in Healthy Adults***

Parameters	Children with Tinea Capitis ($n = 12$)	Healthy Adults ($n = 16$)	Statistical Comparison
Age (yr)	8 ± 2	26 ± 4	—
Weight (kg)	26 ± 5	64 ± 6	—
C_{max} (μg/mL)	0.706 ± 0.277	0.565 ± 0.329	NS
T_{max} (hr)	2.1 ± 1.1	5 ± 0.7	NS
$AUC_{0-\infty}$ (μg/mL/hr)	2.967 ± 0.965	2.135 ± 1.131	$p < .05$
$t_{1/2}\beta$ (hr)	14.7 ± 4.3	27 ± 12	$p < .001$

Modified from Jones TC. Overview of the use of terbinafine (Lamisil) in children. *Br J Dermatol* 1995;132:683-9.
*Mean values ± SD
$AUC_{0-\infty}$, Area under the concentration versus time curve from zero to infinity; C_{max}, peak plasma concentration; *NS,* not significant; $t_{1/2}\beta$, elimination half-life; T_{max}, time until occurrence of peak plasma concentration.

significant adverse effects include mostly reversible loss of taste and/or smell; severe skin eruptions, including generalized erythematous pustulosis and drug-induced lupus erythematosus; Stevens-Johnson syndrome; blood dyscrasias; visual disturbances; and depressive symptoms.[2] No evidence indicates that these idiosyncratic effects are increasing in incidence with the increasing use of terbinafine.[409] Terbinafine has not been shown to be carcinogenic or mutagenic; its use is not recommended during pregnancy or in nursing mothers.

Several clinical studies have documented the safety of terbinafine in pediatric patients.* Terbinafine, administered for a median duration of 4 weeks (range, 1 to 28 weeks) was safe in children between 2 and 17 years of age who received the drug for various dermatophyte and yeast infections of the skin: of a total of 196 patients enrolled in six studies, 22 adverse events were observed in 15 patients. Adverse events probably associated with the use of terbinafine occurred in 6 of these patients (3%), but in none of these patients did terbinafine therapy have to be discontinued.[276] Terbinafine was similarly well tolerated in two double-blind, randomized trials in children with tinea capitis.[155,174,330]

Drug Interactions. Multiple CYP450 enzymes are involved in the metabolism of terbinafine. However, with the possible exception of CYP2D6 substrates, in vitro studies revealed little or no effect on the metabolism of many characteristic CYP substrates.[569] Inhibition of CYP2D6-mediated metabolism may be relevant with the concomitant use of tricyclic antidepressants, β blockers, selective serotonin reuptake inhibitors, and type B monoamine oxidase inhibitors.

In clinical interaction studies, no pharmacokinetic or pharmacodynamic interactions were observed with the concomitant administration of terfenadine,[464] midazolam,[8] and alfentanil.[478] Terbinafine can (1) reduce the clearance of theophylline[543]; (2) increase levels of nortryptiline,[558] amitryptiline,[89] desipramine,[335] imipramine,[533] and paroxetine[624]; (3) increase or reduce warfarin exposure[224,596]; and (4) reduce the trough cyclosporine concentration in patients with transplants.[331] Clearance of terbinafine may be decreased by cimetidine and increased by rifampin.[207]

Clinical Indications. Terbinafine is approved by the FDA in patients older than 18 years of age for the treatment of onychomycosis of toenails and fingernails caused by dermatophytes. It may be indicated for treatment of other superficial infections of the skin and its appendages caused by dermatophytes,[2,41,173] for cutaneous and lymphocutaneous sporotrichosis[98,260] subcutaneous phaeohyphomycosis[69,450] (see Tables 239-4 and 239-15), and, investigationally, for seborrhoic dermatitis.[566] Recommended durations of treatment for tinea capitis, tinea corporis, and tinea pedis, fingernail onychomycosis, and toenail onychomycosis in adults are 4, 2, 6, and 12 weeks, respectively.[274,502]

Several studies have explored the clinical efficacy of terbinafine in children and adolescents.* The overall mycologic and clinical efficacy for 152 children aged 2 to 17 years with various dermatophyte and yeast infections of the skin exceeded 95 percent.[274] In a prospective, randomized clinical trial in 210 children comparing treatment with 4 weeks of terbinafine versus 8 weeks of griseofulvin for *Trichophyton* tinea capitis, both regimens showed overall similar efficacy.[175] In a subsequent study of the duration of treatment in 176 patients, both 2 and 4 weeks of treatment were clinically superior to a 1-week regimen and had similar treatment efficacy, a finding suggesting that a 2-week course may be sufficient for patients with *Trichophyton* tinea capitis.[174] A similar study

*References 79, 86, 174, 175, 226, 274, 300, 330, 393, 508.

*References 79, 86, 175, 175, 274, 300, 330, 393, 508.

performed in 134 patients with *Microsporon* tinea capitis investigating 6, 8, 10, or 12 weeks of therapy demonstrated that 6 weeks of therapy were equivalent to griseofulvin.[330] Finally, a meta-analysis of six randomized, comparative clinical trials indicated that a 2- to 4-week course of terbinafine was at least as effective as a 6- to 8-week course of griseofulvin for the treatment of tinea capitis caused by *Trichophyton* spp.[165]

The broad-spectrum fungicidal in vitro activity, systemic availability, and lack of significant side effects suggested potential usefulness of terbinafine against deep-seated fungal infections. However, terbinafine was ineffective in animal models of pulmonary and disseminated aspergillosis,[287,495] systemic sporotrichosis,[277] cerebral phaeohyphomycosis, disseminated candidiasis, and pulmonary cryptococcosis,[473] findings explained by nonsaturable protein-binding kinetics.[495] Against experimental pulmonary pneumocystosis, terbinafine was active in some,[107,108] but not all,[593] models.

TOPICAL ANTIFUNGAL AGENTS

Apart from fungal keratitis, the use of topical antifungal agents is confined to superficial infections of the skin and mucosal surfaces. The decision to treat superficial infections of the skin and mucosal surfaces with a topical or systemic agent depends mainly on the site and extent of the infection. Immunocompromised children, however, usually require systemic therapies, as do patients with tinea capitis and onychomycosis (see Tables 239-15 and 239-16).[154]

Topical Therapeutics for Superficial Skin Infections

Dermatophytosis is caused by the filamentous fungi *Microsporon* spp., *Trichophyton* spp., and *Epidermophyton floccosum*. Many different agents and formulations are available for topical treatment of dermatophytic skin infections (i.e., tinea corporis, facialis, or pedis), including allylamines and azoles. Agents for treatment of *Candida* dermatitis and tinea (pityriasis) versicolor (caused by *Malassezia furfur* or *Malassezia pachydermatidis*) include various topical azoles and topical polyenes. Most topical agents are applied twice daily well beyond the clinical resolution of the infection. A detailed review of the pharmacologic properties of these topical drugs and of the treatment of cutaneous mycoses is beyond the scope of this chapter and can be found elsewhere.[154,173,257]

Topical Therapeutics For Mucosal Candidiasis

Agents for the topical treatment of vulvovaginal candidiasis include a large variety of antifungal azoles and the polyene nystatin.[53,518] Azole agents may be absorbed to a minor extent and potentially can interfere with the metabolism of concomitant drugs. For example, potentiation of the anticoagulatory effects of acenocoumarol was noted after vaginal administration of miconazole capsules to two postmenopausal patients[313] and after oral administration of miconazole gel in three elderly patients with oral candidiasis.[405]

Antifungal azoles such as clotrimazole and miconazole and antifungal polyenes such as amphotericin B and nystatin are effective in the treatment of oropharyngeal candidiasis. Many clinical trials evaluated the usefulness of these agents for prevention of fungal infections in immunocompromised patients with cancer or HSCT. Although most agents have documented efficacy in the prevention of oropharyngeal candidiasis, they are not effective in preventing invasive mycoses and in improving infection-related and overall mortality in this setting.*

FUTURE DIRECTIONS

Pediatric age groups display important differences in host biology, predisposing conditions, epidemiology, and presentation of fungal infections relative to the adult population. Since the late 1990s, major advances have been made in the field of medical mycology. Most importantly, an array of new antifungal agents has entered the clinical arena. Although the final pediatric approval of some of these agents remains to be established, the development of pediatric therapies has moved forward in an exemplary manner. Invasive fungal infections will remain important causes of morbidity and mortality in immunocompromised pediatric patients. The availability of alternative therapeutic options is an important advance; at the same time, however, antifungal therapy has become increasingly complex. In addition to information on prior antifungal therapies, microbiologic data, existing comorbidities, and concurrent medications, detailed knowledge of the available antifungal armamentarium and contemporary clinical trials is needed more than ever in the management of the individual patient.

CHAPTER 240

DRUGS FOR PARASITIC INFECTIONS

With increasing travel, immigration, use of immunosuppressive drugs and the spread of AIDS, physicians anywhere may see infections caused by parasites. The table below lists first-choice and alternative drugs for most parasitic infections. The table that begins on page 3351 summarizes the known prenatal risks of antiparasitic drugs. The brand names and manufacturers of the drugs are listed in the table on page 3354.

Infection		Drug	Adult dosage	Pediatric dosage
Acanthamoeba keratitis				
Drug of choice:		See footnote 1		
Amebiasis *(Entamoeba histolytica)*				
Asymptomatic				
Drug of choice:		Iodoquinol[2]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
	OR	Paromomycin[3]	25-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
	OR	Diloxanide furoate[4*]	500 mg PO tid × 10 d	20 mg/kg/d PO in 3 doses × 10 d

Infection		Drug	Adult dosage	Pediatric dosage
Mild to Moderate Intestinal Disease				
Drug of choice:[5]		Metronidazole	500-750 mg PO tid × 7-10 d	35-50 mg/kg/d PO in 3 doses × 7-10 d
	OR	Tinidazole[6]	2 g once PO daily × 3 d	≥3 yrs: 50 mg/kg/d (max. 2 g) PO in 1 dose × 3 d
		either followed by		
		Iodoquinol[2]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
	OR	Paromomycin[3*]	25-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
Severe Intestinal and Extraintestinal Disease				
Drug of choice:		Metronidazole	750 mg PO tid × 7-10 d	35-50 mg/kg/d PO in 3 doses × 7-10 d
	OR	Tinidazole[6]	2 g once PO daily × 5 d	≥3 yrs: 50 mg/kg/d (max. 2 g) PO in 1 dose × 5 d
		either followed by		
		Iodoquinol[2]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
	OR	Paromomycin[3*]	25-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
Amebic Meningoencephalitis, primary and granulomatous				
Naegleria fowleri				
Drug of choice:		Amphotericin B[7,8]	1.5 mg/kg/d IV in 2 doses × 3 d, then 1 mg/kg/d × 6 d plus 1.5 mg/d intrathecally × 2 d, then 1 mg/d every other day × 8 d	1.5 mg/kg/d IV in 2 doses × 3 d, then 1 mg/kg/d × 6 d plus 1.5 mg/d intrathecally × 2 d, then 1 mg/d every other day × 8 d
Acanthamoeba spp.				
Drug of choice:		See footnote 9		

*Availability problems. See table on page 3327.

1. Keratitis is typically associated with contact lens use (FR Carvalho et al, Cornea 2009; 28:516). Topical 0.02% chlorhexidine and polyhexamethylene biguanide (PHMB, 0.02%), either alone or in combination, have been used successfully in a large number of patients. Treatment with either chlorhexidine or PHMB is often combined with propamidine isethionate *(Brolene)* or hexamidine *(Desmodine).* None of these drugs is commercially available or approved for use in the US, but they can be obtained from compounding pharmacies (see footnote 4). Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773; www.leiterrx.com) is a compounding pharmacy that specializes in ophthalmic drugs. Propamidine is available over the counter in the UK and Australia. Hexamidine is available in France. The combination of chlorhexidine, natamycin (pimaricin) and debridement also has been successful (K Kitagawa et al, Jpn J Ophthalmol 2003; 47:616), as has 0.1% sodium diclofenac (AL Agahan et al, Ann Acad Med Singapore 2009; 38: 175) in a small series of 3 patients. Debridement is most useful during the stage of corneal epithelial infection; keratoplasty in medically unresponsive keratitis was successful in 31 patients (AS Kitzmann et al, Ophthalmology 2009; 116: 864). Most cysts are resistant to neomycin; its use is no longer recommended. Azole antifungal drugs (ketoconazole, itraconazole) have been used as oral or topical adjuncts. Use of corticosteroids is controversial. Prolonged therapy (≥6 months) may be necessary (JK Dart et al, Am J Ophthalmol 2009; 148:487).
2. Iodoquinol should be taken after meals.
3. Paromomycin should be taken with a meal.
4. Not available commercially. It may be obtained through compounding pharmacies such as Expert Compounding Pharmacy, 6744 Balboa Blvd, Lake Balboa, CA 91406 (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-7064). Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com).
5. Nitazoxanide may be effective against a variety of protozoan and helminth infections (DA Bobak, Curr Infect Dis Rep 2006; 8:91; E Diaz et al, Am J Trop Med Hyg 2003; 68:384). It is effective against mild to moderate amebiasis, 500 mg bid × 3 d (JF Rossignol et al, Trans R Soc Trop Med Hyg 2007; 101:1025; AE Escobedo et al, Arch Dis Child 2009; 94:478). It is FDA-approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium* (Med Lett Drugs Ther 2003; 45:29). Nitazoxanide is available in 500-mg tablets and an oral suspension; it should be taken with food.
6. A nitroimidazole similar to metronidazole, tinidazole appears to be as effective as metronidazole and better tolerated (Med Lett Drugs Ther 2004; 46:70). It should be taken with food to minimize GI adverse effects. For children and patients unable to take tablets, a pharmacist can crush the tablets and mix them with cherry syrup (*Humco*, and others). The syrup suspension is good for 7 days at room temperature and must be shaken before use (HB Fung and TL Doan, Clin Ther 2005; 27:1859). Ornidazole, a similar drug, is also used outside the US.

Infection		Drug	Adult dosage	Pediatric dosage
Balamuthia mandrillaris				
Drug of choice:		See footnote 10		
Sappinia diploidea				
Drug of choice:		See footnote 11		
Ancylostoma caninum (Eosinophilic enterocolitis)				
Drug of choice:		Albendazole[7,12]	400 mg PO once	400 mg PO once
	OR	Mebendazole	100 mg PO bid × 3 d	100 mg PO bid × 3 d
	OR	Endoscopic removal		
Ancylostoma duodenale, see HOOKWORM				
Angiostrongyliasis *(Angiostrongylus cantonensis, Angiostrongylus costaricensis)*				
Drug of choice:		See footnote 13		
Anisakiasis *(Anisakis* spp.**)**				
Treatment of choice:[14]	Surgical or endoscopic removal			
Ascariasis *(Ascaris lumbricoides,* roundworm)				
Drug of choice:[5]		Albendazole[7,12]	400 mg PO once	400 mg PO once
	OR	Mebendazole	100 mg bid PO × 3 d or 500 mg once	100 mg PO bid × 3 d or 500 mg once
	OR	Ivermectin[7,15]	150-200 mcg/kg PO once	150-200 mcg/kg PO once

7. Not FDA-approved for this indication.
8. A *Naegleria fowleri* infection was treated successfully in a 9-year old girl with combination of amphotericin B and miconazole (both drugs given intravenously and intrathecally) plus oral rifampin (JS Seidel et al NEJM 1982; 306:346). While amphotericin B and miconazole appear to have a synergistic effect, Medical Letter consultants believe the rifampin probably had no additional effect (GS Visvesvara et al, FEMS Immunol Med Microbiol 2007; 50:1). Parenteral miconazole is no longer available in the US. Azithromycin (changed to clarithromycin during therapy because of toxicity concerns and for better CNS penetration) has been used in multidrug combination regimens to treat *Balamuthia* infection. *In vitro*, azithromycin is more active than clarithromycin against *Naegleria*, so may be a better choice combined with amphotericin B for treatment of *Naegleria* (TR Deetz et al, Clin Infect Dis 2003; 37:1304; FL Schuster and GS Visvesvara, Drug Resistance Updates 2004; 7:41).Combinations of amphotericin B, ornidazole and rifampin (R Jain et al, Neurol India 2002; 50:470), amphotericin B, fluconazole (IV and PO) and rifampin (J Vargas-Zepeda et al, Arch Med Research 2005;36:83) and amphotericin B, chloramphicol and rifampacin have also been used (R Rai et al, Indian Pediatr 2008; 45:1004). Case reports of other successful therapy have been published (FL Schuster and GS Visvesvara, Int J Parasitol 2004; 34:1001).
9. Several patients with granulomatous amebic encephalitis (GAE) have been successfully treated with combinations of pentamidine, sulfadiazine, flucytosine, and either fluconazole or itraconazole (GS Visvesvara et al, FEMS Immunol Med Microbiol 2007; 50:1). GAE in an AIDS patient was treated successfully with sulfadiazine, pyrimethamine and fluconazole combined with surgical resection of the CNS lesion (M Seijo Martinez et al, J Clin Microbiol 2000; 38:3892). Chronic *Acanthamoeba* meningitis was successfully treated in 2 children with a combination of oral trimethoprim/sulfamethoxazole, rifampin and ketoconazole (T Singhal et al, Pediatr Infect Dis J 2001; 20:623). Disseminated cutaneous infection in an immunocompromised patient was treated successfully with IV pentamidine, topical chlorhexidine and 2% ketoconazole cream, followed by PO itraconazole (CA Slater et al, N Engl J Med 1994; 331:85) and with voriconazole and amphotericin B lipid complex (R Walia et al,Transplant Infect Dis 2007; 9:51). Other reports of successful therapy have been described (FL Schuster and GS Visvesvara, Drug Resistance Updates 2004; 7:41; AC Aichelburg et al, Emerg Infect Dis 2008; 14:1743). Susceptibility testing of *Acanthamoeba* isolates has shown differences in drug sensitivity between species and even among strains of a single species; antimicrobial susceptibility testing is advisable (FL Schuster and GS Visvesvara, Int J Parasitiol 2004; 34:1001).
10. *B. mandrillaris* is a free-living ameba that causes subacute to fatal granulomatous amebic encephalitis (GAE) and cutaneous disease (MMWR 2008; 57:768; FL Schuster et al, Clin Infect Dis 2009; 48:879). Three cases of *Balamuthia* encephalitis have been successfully treated with pentamidine, flucytosine, fluconazole and sulfadiazine plus either azithromycin or clarithromycin combined with surgical resection of the CNS lesion; in two cases flucytosine was given as well. Clarithromycin may have less toxicity and better penetration into CSF than azithromycin (TR Deetz et al, Clin Infect Dis 2003; 37:1304; S Jung et al, Arch Pathol Lab Med 2004; 128:466).
11. A free-living ameba that may rarely be pathogenic to humans (GS Visvesvara et al, FEMS Immunol Med Microbiol 2007; 50:1; F Marciano-Cabral, J Infect Dis 2009; 199: 1104). *S. diploidea* has been successfully treated with azithromycin, pentamidine, itraconazole and flucytosine combined with surgical resection of the CNS lesion (BB Gelman et al, J Neuropathol Exp Neurol 2003; 62:990).
12. Albendazole must be taken with food; a fatty meal increases oral bioavailability.
13. *A. cantonensis* causes predominantly neurotropic disease (QP Wang et al, Lancet Infect Dis 2008; 8:621). *A. costaricensis* causes gastrointestinal disease. Most patients infected with either species have a self-limited course and recover completely. Analgesics, corticosteroids and periodic removal of CSF can relieve symptoms from increased intracranial pressure (L Ramirez-Avila et al, Clin Infect Dis 2009; 48:322). Treatment of *A. cantonensis* is controversial and varies across endemic areas. No antihelminthic drug is proven to be effective and some patients have worsened with therapy. Mebendazole or albendazole each with or without a corticosteroid appear to shorten the course of infection (K Sawanyawisuth and K Sawanyawisuth, Trans R Soc Trop Med Hyg 2008; 102:990; V Chotmongkol et al. Am J Trop Med Hyg 2009; 81:443).

Infection		Drug	Adult dosage	Pediatric dosage
Babesiosis				
Drug of choice:[16]		Atovaquone[7,17]	750 mg PO bid × 7-10 d	40 mg/kg/d PO in 2 doses × 7-10 d
		plus azithromycin[7]	500-1000 mg PO on d1, then 250-1000 mg PO on d2-10	10 mg/kg (max 500 mg/dose) PO on d 1, then 5 mg/kg/d (max 250 mg dose) PO on d 2-10
	OR	Clindamycin[7,18]	300-600 mg IV qid or 600 mg PO tid × 7-10 d	20-40 mg/kg/d PO in 3 doses × 7-10 d
		plus quinine[7,19]	650 mg PO tid × 7-10 d	30 mg/kg/d PO in 3 doses × 7-10 d
Balamuthia mandrillaris, see AMEBIC MENINGOENCEPHALITIS, PRIMARY				
Balantidiasis *(Balantidium coli)*				
Drug of choice:		Tetracycline[7,20]	500 mg PO qid × 10 d	40 mg/kg/d (max. 2 g) PO in 4 doses × 10 d
Alternative:		Metronidazole[7]	500-750 mg PO tid × 5 d	35-50 mg/kg/d PO in 3 doses × 5 d
	OR	Iodoquinol[2,7]	650 mg PO tid × 20 d	30-40 mg/kg/d (max 2 g) PO in 3 doses × 20 d
Baylisascariasis *(Baylisascaris procyonis)*				
Drug of choice:		See footnote 21		
***Blastocystis* spp. infection**				
Drug of choice:		See footnote 22		
Capillariasis *(Capillaria philippinensis)*				
Drug of choice:		Mebendazole[7]	200 mg PO bid × 20 d	200 mg PO bid × 20 d
Alternative:		Albendazole[7,12]	400 mg PO daily × 10 d	400 mg PO daily × 10 d

14. Gastric anisakiasis can usually be diagnosed and treated by endoscopic removal of the worm. Enteric anisakiasis is more difficult to diagnose; it can be managed without worm removal as the worms eventually die. Surgery may be needed in the event of intestinal obstruction or peritonitis (A Repiso Ortega et al, Gastroenterol Hepatol 2003; 26:341; K Nakaji, Intern Med 2009; 48:573). Successful treatment of anisakiasis with albendazole 400 mg PO bid × 3-5 d has been reported, but diagnosis was presumptive (DA Moore et al, Lancet 2002; 360:54; E Pacios et al, Clin Infect Dis 2005; 41:1825).
15. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established. Ivermectin should be taken on an empty stomach with water (NM Fox, Curr Opin Infect Dis 2006; 19:588).
16. E Vannier et al, Infect Dis Clin North Am 2008; 22:469; GP Wormser et al, Clin Infect Dis 2006; 43:1089. *B. microti* is most common in the US. Most disease in Europe is attributed to *B. divergens* and is generally more severe. Several cases caused by various *B. divergens*-like agents have also been documented in the US (BL Herwaldt et al, Emerg Infect Dis 2004; 10:622). Exchange transfusion has been used in combination with drug treatment in severely ill patients and those with high (>10%) parasitemia. In non-immunosuppressed patients infected with *B. microti* who were not severely ill, combination therapy with atovaquone and azithromycin was as effective as clindamycin and quinine and better tolerated (PJ Krause et al, N Engl J Med 2000; 343:1454). Immunosuppressed patients and those with asplenia should be treated a minimum of 6 weeks and at least 2 weeks past the last positive smear. Resistance to azithromycin-atovaquone treatment has been reported in immunocompromised patients (GP Wormser et al. Clin Infect Dis 2010; 50:381). Some patients may be co-infected with the etiologic agents of Lyme disease and human granulocytic anaplasmosis.
17. Atovaquone is available in an oral suspension that should be taken with a meal to increase absorption.
18. Oral clindamycin should be taken with a full glass of water to minimize esophageal ulceration.
19. Quinine should be taken with or after a meal to decrease gastrointestinal adverse effects.
20. Use of tetracyclines is contraindicated in pregnancy and in children <8 years old. Tetracycline should be taken 1 hour before or 2 hours after meals and/or dairy products.
21. No drug has been demonstrated to be effective. Albendazole 25 mg/kg/d PO × 20 d started as soon as possible (up to 3 d after possible infection) might prevent clinical disease and is recommended for children with known exposure (ingestion of raccoon stool or contaminated soil) (WJ Murray and KR Kazacos, Clin Infect Dis 2004; 39:1484). Mebendazole, levamisole or ivermectin could be tried if albendazole is not available. Steroid therapy may be helpful, especially in eye and CNS infections (PJ Gavin et al, Clin Microbiol Rev 2005; 18:703). Ocular baylisascariasis has been treated successfully using laser photocoagulation therapy to destroy the intraretinal larvae (CA Garcia et al, Eye (Lond) 2004; 18:624).
22. Blastocystis has been reclassified as a fungus. Clinical significance of these organisms is controversial; metronidazole 750 mg PO tid × 10 d, iodoquinol 650 mg PO tid × 20 d or trimethoprim/sulfamethoxazole 1 DS tab PO bid × 7 d have been reported to be effective (KS Tan, Clin Microbiol Rev 2008; 21:639). Metronidazole resistance may be common in some areas (J Yakoob et al, Br J Biomed Sci 2004; 61:75). Nitazoxanide has been effective in clearing organisms and improving symptoms (E Diaz et al, Am J Trop Med Hyg 2003; 68:384; JF Rossignol, Clin Gastroenterol Hepatol 2005; 3:987).

Infection	Drug	Adult dosage	Pediatric dosage
Chagas' disease, see TRYPANOSOMIASIS			
Clonorchis sinensis, see FLUKE infection			
Cryptosporidiosis *(Cryptosporidium)*			
Non-HIV Infected			
Drug of choice:	Nitazoxanide[5]	500 mg PO bid × 3 d	1-3 yrs: 100 mg PO bid × 3 d 4-11 yrs: 200 mg PO bid × 3 d >12 yrs: 500 mg PO bid × 3 d
HIV Infected			
Drug of choice:	See footnote 23		
Cutaneous Larva Migrans (creeping eruption, dog and cat hookworm)			
Drug of choice:[24]	Albendazole[7,12]	400 mg PO daily × 3 d	400 mg PO daily × 3 d
OR	Ivermectin[7,15]	200 mcg/kg PO daily × 1-2 d	200 mcg/kg PO daily × 1-2 d
Cyclosporiasis *(Cyclospora cayetanensis)*			
Drug of choice:[25]	Trimethoprim/ sulfamethoxazole[7]	TMP 160 mg/SMX	TMP 10 mg/kg/SMX
		800 mg (1 DS tab) PO bid × 7-10 d	50 mg/kg/d PO in 2 doses × 7-10 d
Alternative:	Ciprofloxacin[7]	500 mg PO bid × 7 d	–
Cysticercosis, see TAPEWORM infection			
Cystoisosporiasis *(Cystoisospora belli,* formerly known as *Isospora)*			
Drug of choice:[26]	Trimethoprim-sulfamethoxazole[7]	TMP 160 mg/SMX 800 mg (1 DS tab) PO bid × 10 d	TMP 10 mg/kg/d/SMX 50 mg/kg/d PO in 2 doses × 10 d
Dientamoeba fragilis infection[27]			
Drug of choice:[28]	Iodoquinol[2,7]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
OR	Paromomycin[3,7*]	25-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
OR	Metronidazole[7]	500-750 mg PO tid × 10 d	35-50 mg/kg/d PO in 3 doses × 10 d
Diphyllobothrium latum, see TAPEWORM infection			
Dracunculus medinensis **(guinea worm) infection**			
Drug of choice:	See footnote 29		

23. No drug has proven efficacy against cryptosporidiosis in advanced AIDS (I Abubakar et al, Cochrane Database Syst Rev 2007; 1:CD004932). Potent antiretroviral therapy (ART) is the mainstay of treatment. Nitazoxanide, paromomycin, or a combination of paromomycin and azithromycin may be tried to decrease diarrhea and recalcitrant malabsorption of antimicrobial drugs, which can occur with chronic cryptosporidiosis (B Pantenburg et al, Expert Rev Anti InfectTher 2009; 7:385).
24. J Heukelbach and H Feldmeier, Lancet Infect Dis 2008; 8:302.
25. CA Warren, Curr Infect Dis Rep 2009; 11:108. In one study of HIV-infected patients with *Cyclospora* infection, ciprofloxacin treatment led to resolution in 87% of patients compared to 100% with TMP/SMX (RI Verdier et al, Ann Intern Med 2000; 132:885). HIV-infected patients may need higher dosage and long-term maintenance. Nitazoxanide (see also footnote 5) has also been used in a few patients (SM Zimmer et al, Clin Infect Dis 2007; 44:466; E Diaz et al, Am J Trop Med Hyg 2003; 68:384).
26. *Isospora belli* has been renamed and included the *Cystoisospora* genus. Usually a self-limited illness in immunocompetent patients. Immunosuppressed patients may need higher doses and longer duration (TMP/SMX qid for up to 3 to 4 weeks (Morbid Mortal Wkly Rep 2009; 58 RR4:1). They may require secondary prophylaxis (TMP/SMX DS tiw). In sulfa-allergic patients, pyrimethamine 50-75 mg daily in divided doses (plus leucovorin 10-25 mg/d) has been effective.
27. DJ Stark et al, Trends Parasitol 2006; 22:92; O Vandenberg et al, Pediatr Infect Dis J 2007; 26:88.
28. In one study, single-dose ornidazole, a nitroimidazole similar to metronidazole that is available in Europe, was effective and better tolerated than 5 days of metronidazole (O Kurt, Clin Microbiol Infect 2008; 14:601).
29. No drug is curative against *Dracunculus*. A program for monitoring local sources of drinking water to eliminate transmission has dramatically decreased the number of cases worldwide. The treatment of choice is slow extraction of worm combined with wound care and pain management (Morbid Mortal Wkly Rep 2009; 58:1123).
30. Since family members are usually infected, treatment of the entire household is recommended; retreatment after 14-21 d may be needed.
31. Pyrantel pamoate suspension can be mixed with milk or fruit juice.

Infection	Drug	Adult dosage	Pediatric dosage
Echinococcus, see TAPEWORM infection			
***Entamoeba histolytica*, see AMEBIASIS**

Drug of choice:[40]	Diethylcarbamazine*	6 mg/kg/d PO in 3 doses × 12 d[36]	6 mg/kg/d PO in 3 doses × 12 d[36]
OR	Ivermectin[7,15]	150 mcg/kg PO once	150 mcg/kg PO once
***Tropical Pulmonary Eosinophilia (TPE)*[41]**			
Drug of choice:	Diethylcarbamazine*	6 mg/kg/d in 3 doses × 12-21 d[36]	6 mg/kg/d in 3 doses × 12-21 d[36]
Onchocerca volvulus (River blindness)			
Drug of choice:	Ivermectin[15,42]	150 mcg/kg PO once, repeated every 6-12 mos until asymptomatic	150 mcg/kg PO once, repeated every 6-12 mos until asymptomatic

34. Most symptoms are caused by adult worm. A single-dose combination of albendazole (400 mg PO) with either ivermectin (200 mcg/kg PO) or diethylcarbamazine (6 mg/kg PO) is effective for reduction or suppression of *W. bancrofti* microfilaria; none of these drug combinations kills all the adult worms (D Addiss et al, Cochrane Database Syst Rev 2004; CD003753).
35. For patients with microfilaria in the blood, Medical Letter consultants start with a lower dosage and scale up: d1: 50 mg; d2: 50 mg tid; d3: 100 mg tid; d4-14: 6 mg/kg/d in 3 doses (for *Loa Loa* d4-14: 9 mg/kg/d in 3 doses). Multi-dose regimens have been shown to provide more rapid reduction in microfilaria than single-dose diethylcarbamazine, but microfilaria levels are similar 6-12 months after treatment (LD Andrade et al, Trans R Soc Trop Med Hyg 1995; 89:319; PE Simonsen et al, Am J Trop Med Hyg 1995; 53:267). A single dose of 6 mg/kg is used in endemic areas for mass treatment, but there are no studies directly comparing the efficacy of the single-dose regimen to a 12-day course. It should be used cautiously in geographic regions where *O. volvulus* coexists with other filariae. One review concluded that the 12-day regimen did not have a higher macrofilaricidal effect than single dose (A Hoerauf, Curr Opin Infect Dis 2008; 21: 673; J Figueredo-Silva et al, Trans R Soc Trop Med Hyg 1996; 90:192; J Noroes et al, Trans R Soc Trop Med Hyg 1997; 91:78).
32. Antihistamines or corticosteroids may be required to decrease allergic reactions to components of disintegrating microfilariae that result from treatment, especially in infection caused by *Loa loa*.
33. Endosymbiotic *Wolbachia* bacteria, which are present in most human filariae except *Loa loa*, are essential to filarial growth, development, embryogenesis and survival and represent an additional target for therapy. Doxycycline 100 or 200 mg/d PO × 6-8 wks in lymphatic filariasis, onchocerciasis, and *Mansonella perstans* has resulted in substantial loss of *Wolbachia* and decrease in both micro- and macrofilariae (MJ Bockarie et al, Expert Rev Anti Infect Ther 2009; 7:595; A Hoerauf Curr Opin Infect Dis 2008; 21:673;YI Coulibaly et al, N Engl J Med 2009; 361:1448). Use of tetracyclines is contraindicated in pregnancy and in children <8 yrs old.
36. Diethylcarbamazine should not be used for treatment of *Onchocerca volvulus* due to the risk of increased ocular side effects (including blindness) associated with rapid killing of the worms. It should be used cautiously in geographic regions where *O. volvulus* coexists with other filariae. Diethylcarbamazine is contraindicated during pregnancy. See also footnote 42.
37. In heavy infections with *Loa loa*, rapid killing of microfilariae can provoke encephalopathy. Apheresis has been reported to be effective in lowering microfilarial counts in patients heavily infected with *Loa loa* (EA Ottesen, Infect Dis Clin North Am 1993; 7:619). Albendazole may be useful for treatment of loiasis when diethylcarbamazine is ineffective or cannot be used, but repeated courses may be necessary (AD Klion et al, Clin Infect Dis 1999; 29:680; TE Tabi et al, Am J Trop Med Hyg 2004; 71:211). Ivermectin has also been used to reduce microfilaremia, but albendazole is preferred because of its slower onset of action and lower risk of precipitating encephalopathy (AD Klion et al, J Infect Dis 1993; 168:202; M Kombila et al, Am J Trop Med Hyg 1998; 58:458). Diethylcarbamazine, 300 mg PO once/wk, has been recommended for prevention of loiasis (TB Nutman et al, N Engl J Med 1988; 319:752).

Infection	Drug	Adult dosage	Pediatric dosage
Fluke, hermaphroditic, infection			
Clonorchis sinensis (Chinese liver fluke)[43]			
Drug of choice:	Praziquantel[44]	75 mg/kg/d PO in 3 doses × 2 d	75 mg/kg/d PO in 3 doses × 2 d
OR	Albendazole[7,12]	10 mg/kg/d PO × 7 d	10 mg/kg/d PO × 7 d
Fasciola Hepatica (sheep liver fluke)[43]			
Drug of choice:[45]	Triclabendazole*	10 mg/kg PO once or twice	10 mg/kg PO once or twice
Alternative:	Bithionol*	30-50 mg/kg on alternate days × 10-15 doses	30-50 mg/kg on alternate days × 10-15 doses
OR	Nitazoxanide[5,7]	500 mg PO bid × 7 d	1-3 yrs: 100 mg PO bid × 7 d 4-11 yrs: 200 mg PO bid × 7 d >12 yrs: 500 mg PO bid × 7 d
Fasciolopsis buski, Heterophyes heterophyes, Metagonimus yokogawai (intestinal flukes)			
Drug of choice:	Praziquantel[7,44]	75 mg/kg/d PO in 3 doses × 1 d	75 mg/kg/d PO in 3 doses × 1 d
Metorchis conjunctus *(North American liver fluke)*			
Drug of choice:	Praziquantel[7,44]	75 mg/kg/d PO in 3 doses × 1 d	75 mg/kg/d PO in 3 doses × 1 d
Nanophyetus salmincola			
Drug of choice:	Praziquantel[7,44]	60 mg/kg/d PO in 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d
Opisthorchis viverrini *(Southeast Asian liver fluke)*[43]			
Drug of choice:	Praziquantel[44]	75 mg/kg/d PO in 3 doses × 2 d	75 mg/kg/d PO in 3 doses × 2 d
Paragonimiasis (P.westermani, P. miyazaki, P. skrjabini, P. hueitungensis, P. heterotrema, P. utcerobilaterus, P. Africanus, P. Mexicanus, P. Kellicotti,) (lung fluke)			
Drug of choice:	Praziquantel[7,44]	75 mg/kg/d PO in 3 doses × 2 d	75 mg/kg/d PO in 3 doses × 2 d
Alternative:	Triclabendazole[46*]	10 mg/kg PO once or twice	10 mg/kg PO once or twice
	Bithionol*	30-50 mg/kg on alternate days × 10-15 doses	30-50 mg/kg on alternate days × 10-15 doses

38. Diethylcarbamazine has no effect. A single dose of ivermectin 200 mcg/kg PO reduces microfilaria densities and provides both short- and long-term reductions in *M. ozzardi* microfilaremia (AA Gonzalez et al, W Indian Med J 1999; 48:231).
39. One small study compared single-dose ivermectin to albendazole alone or the two together although the combination reduced microfilaremia 1 and 3 months post treatment, the effect was not significant at 6 and 12 months (SM Asio et al, Ann Trop Med Parasitol 2009; 103:31).
40. Diethylcarbamazine is potentially curative due to activity against both adult worms and microfilariae. Ivermectin is active only against microfilariae.
41. VK Vijayan, Curr Opin Pulm Med 2007; 13:428. Relapses occur and can be treated with a repeated course of diethylcarbamazine.
42. Diethylcarbamazine should not be used for treatment of this disease because rapid killing of the worms can lead to blindness. Periodic treatment with ivermectin (every 3-12 months), 150 mcg/kg PO, can prevent blindness due to ocular onchocerciasis (DN Udall, Clin Infect Dis 2007; 44:53). Skin reactions after ivermectin treatment are often reported in persons with high microfilarial skin densities. Ivermectin has been inadvertently given to pregnant women during mass treatment programs; the rates of congenital abnormalities were similar in treated and untreated women. Because of the high risk of blindness from onchocerciasis, the use of ivermectin after the first trimester is considered acceptable according to the WHO. Addition of 6-8 weeks of doxycycline to ivermectin is increasingly common. Doxycycline (100 mg/day PO for 6 weeks), followed by a single 150 mcg/kg PO dose of ivermectin, resulted in up to 19 months of amicrofilaridermia and 100% elimination of *Wolbachia* species (A Hoerauf et al, Lancet 2001; 357:1415).
43. LA Marcos, Curr Opin Infect Dis 2008; 21:523.
44. Praziquantel should be taken with liquids during a meal.
45. Unlike infections with other flukes, *Fasciola hepatica* infections may not respond to praziquantel. Triclabendazole (*Egaten*—Novartis) appears to be safe and effective, but data are limited (J Keiser et al, Expert Opin Investig Drugs 2005; 14:1513). It is available from Victoria Pharmacy, Zurich, Switzerland (www.pharmaworld.com; 011-4143-344-60-60) and should be given with food for better absorption. Nitazoxanide also appears to have efficacy in treating fascioliasis in adults and in children (L Favennec et al, Aliment Pharmacol Ther 2003; 17:265; JF Rossignol et al, Trans R Soc Trop Med Hyg 1998; 92:103; SM Kabil et al, Curr Ther Res 2000; 61:339).
46. J Keiser et al, Expert Opin Investig Drugs 2005; 14:1513. See footnote 45 for availability.

Infection		Drug	Adult dosage	Pediatric dosage
Giardiasis *(Giardia duodenalis)*				
Drug of choice:		Metronidazole[7]	250 mg PO tid × 5-7 d	15 mg/kg/d PO in 3 doses × 5-7 d
	OR	Tinidazole[6]	2 g PO once	≥3 yrs: 50 mg/kg PO once (max. 2 g)
	OR	Nitazoxanide[5]	500 mg PO bid × 3 d	1-3 yrs: 100 mg PO bid × 3 d 4-11 yrs: 200 mg PO bid × 3 d >12 yrs: 500 mg PO bid × 3 d
Alternative:[47]		Paromomycin[3,7,48*]	25-35 mg/kg/d PO in 3 doses × 5-10 d	25-35 mg/kg/d PO in 3 doses × 5-10 d
	OR	Furazolidone[*]	100 mg PO qid × 7-10 d	6 mg/kg/d PO in 4 doses × 7-10 d
	OR	Quinacrine[4,49*]	100 mg PO tid × 5 d	6 mg/kg/d PO in 3 doses × 5 d (max 300 mg/d)
Gnathostomiasis *(Gnathostoma spinigerum)*[50]				
Treatment of choice:		Albendazole[7,12]	400 mg PO bid × 21 d	400 mg PO bid × 21 d
	OR	Ivermectin[7,15]	200 mcg/kg/d PO × 2 d	200 mcg/kg/d PO × 2 d
		either		
	±	Surgical removal		
Gongylonemiasis *(Gongylonema* **sp.)**[51]				
Treatment of choice:		Surgical removal		
	OR	Albendazole[7,12]	400 mg/d PO × 3 d	400 mg/d PO × 3 d
Hookworm infection *(Ancylostoma duodenale, Necator americanus)*				
Drug of choice:		Albendazole[7,12]	400 mg PO once	400 mg PO once
	OR	Mebendazole	100 mg PO bid × 3 d or 500 mg once	100 mg PO bid × 3 d or 500 mg once
	OR	Pyrantel pamoate[7,31*]	11 mg/kg (max. 1 g) PO daily × 3 d	11 mg/kg (max. 1 g) PO daily × 3 d
Hydatid cyst, see TAPEWORM infection				
***Hymenolepis nana,* see TAPEWORM infection**				
***Isospora belli,* see** *Cystoisospora*				
Leishmaniasis				
Visceral[52,53]				
Drug of choice:		Liposomal amphotericin B[54]	3 mg/kg/d IV d 1-5, 14 and 21[55]	3 mg/kg/d IV d 1-5, 14 and 21[55]
	OR	Sodium stibogluconate[*]	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Meglumine antimonate[*]	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Miltefosine[56,57*]	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d

47. Additional option: albendazole (400 mg/d PO × 5 d in adults and 10 mg/kg/d PO × 5 d in children) (K Yereli et al, Clin Microbiol Infect 2004; 10:527; O Karabay et al, World J Gastroenterol 2004; 10:1215). Refractory disease: standard doses of metronidazole plus quinacrine × 3 wks (TE Nash et al, Clin Infect Dis 2001; 33:22). In one study, nitazoxanide was used successfully in high doses (1.5 g PO bid × 30 d) to treat a case of *Giardia* resistant to metronidazole and albendazole (P Abboud et al, Clin Infect Dis 2001; 32:1792).
48. Poorly absorbed; may be useful for treatment of giardiasis in pregnancy.
49. Quinacrine should be taken with liquids after a meal. It is not available in the US but can be compounded by Gallipot Pharmacy (www.gallipot.com; 800-423-6967).
50. All patients should be treated with medication whether surgery is attempted or not. JS Herman and PL Chiodini, Clin Microbiol Rev 2009; 22:484; L Ramirez-Avila et al, Clin Infect Dis 2009; 48:322.
51. S Pasuralertsakul et al, Am Trop Med Parasitol 2008; 102:455; G Molavi et al, J Helminth 2006; 80:425.
52. To maximize effectiveness and minimize toxicity, the choice of drug, dosage and duration of therapy should be individualized based on the region of disease acquisition, likely infecting species, and host factors such as immune status (BL Herwaldt, Lancet 1999; 354:1191). Some of the listed drugs and regimens are effective only against certain *Leishmania* species/strains and only in certain areas of the world (J Arevalo et al, J Infect Dis 2007; 195:1846). Medical Letter consultants recommend consultation with physicians experienced in management of this disease.
53. Visceral infection is most commonly due to the Old World species *L. donovani* (kala-azar) and *L. infantum* (referred to as *L. chagasi* in the New World).

Infection		Drug	Adult dosage	Pediatric dosage
Alternative:	OR	Amphotericin B[7]	1 mg/kg IV daily × 15-20 d or every second day for up to 8 wks (total usually 15-20 mg/kg)	1 mg/kg IV daily × 15-20 d or every second day for up to 8 wks (total usually 15-20 mg/kg)

Mucosal[52,63]				
Drug of choice:		Sodium stibogluconate[*]	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Meglumine antimonate[*]	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Amphotericin B[7]	0.5-1 mg/kg IV daily or every second day for up to 8 wks	0.5-1 mg/kg IV daily or every second day for up to 8 wks
	OR	Miltefosine[56,64*]	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d
Lice infestation *(Pediculus humanus, P. capitis, Phthirus pubis)*[65]				
Drug of choice:		Pyrethrins with piperonyl butoxide[66]	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
	OR	1% Permethrin[66]	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
	OR	5% Benzyl alcohol lotion[67]	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart
	OR	0.5% Malathion[68]	Topically, 2 × at least 7 d apart	Topically, 2 × at least 7 d apart

54. Liposomal amphotericin B *(AmBisome)* is the only lipid formulation of amphotericin B FDA-approved for treatment of visceral leishmania, largely based on clinical trials in patients infected with *L. infantum* (A Meyerhoff, Clin Infect Dis 1999; 28:42). In one open-label study one 10 mg/kg dose of liposomal amphotericin B was as effective as 15 infusions of amphotericin B (1 mg/kg/d) on alternate days (S Sundar et al, N Engl J Med 2010; 362:504). It is the drug of choice for visceral leishmania in pregnancy. Two other amphotericin B lipid formulations, amphotericin B lipid complex *(Abelcet)* and amphotericin B cholesteryl sulfate *(Amphotec)* have been used, but are considered investigational for this condition and may not be as effective (C Bern et al, Clin Infect Dis 2006; 43:917).
55. The FDA-approved dosage regimen for immunocompromised patients (e.g., HIV infected) is 4 mg/kg/d IV on days 1-5, 10, 17, 24, 31 and 38. The relapse rate is high; maintenance therapy (secondary prevention) may be indicated, but there is no consensus as to dosage or duration.
56. Miltefosine *(Impavido)* is manufactured in 10- or 50-mg capsules by Paladin (Montreal, Canada) and is not available in the US. The drug is contraindicated in pregnancy; a negative pregnancy test before drug initiation and effective contraception during and for 2 months after treatment is recommended (HW Murray et al, Lancet 2005; 366:1561).
57. Miltefosine is effective for both antimony-sensitive and -resistant *L. donovani* (Indian).
58. Paromomycin IM has been effective against *Leishmania* in India; it has not yet been tested in South America or the Mediterranean and there are insufficient data to support its use in pregnancy (S Sundar et al, N Engl J Med 2007; 356:2571; S Sundar and J Chakravarty, Expert Opin Investig Drugs 2008; 17:787). One study in India used a 14-day course of paromomycin (S Sundar et al, Clin Infect Dis 2009; 49:914). Topical paromomycin should be used only in geographic regions where cutaneous leishmaniasis species have low potential for mucosal spread. A formulation of 15% paromomycin/12% methylbenzethonium chloride *(Leshcutan)* in soft white paraffin for topical use has been reported to be partially effective against cutaneous leishmaniasis due to *L. major* in Israel and *L. mexicana* and *L. (V.) braziliensis* in Guatemala, where mucosal spread is very rare (BA Arana et al, Am J Trop Med Hyg 2001; 65:466; DH Kim et al, PLoS Negl Trop Dis 2009; 3:e381). The methylbenzethonium is irritating to the skin; lesions may worsen before they improve.
59. Cutaneous infection is most commonly due to the Old World species *L. major* and *L. tropica* and the New World species *L. mexicana, L. (Vianna) braziliensis, L. (V.) panamensis* and others.
60. In a placebo-controlled trial in patients ≥12 years old, miltefosine was effective for treatment of cutaneous leishmaniasis due to *L.(V.) panamensis* in Colombia, but not *L.(V.) braziliensis* or *L. mexicana* in Guatemala (J Soto et al, Clin Infect Dis 2004; 38:1266). For forms of disease that require long periods of treatment, such as diffuse cutaneous leishmaniasis and post kala-azar dermal leishmaniasis, miltefosine might be a useful treatment (JJ Berman, Expert Opin Drug Metab Toxicol 2008; 4:1209).

Infection		Drug	Adult dosage	Pediatric dosage
Alternative:		Ivermectin[7,15,69]	200 or 400 mcg/kg PO	≥15 kg: 200 or 400 mcg/kg PO

		clindamycin[7,18,82]	20 mg/kg/d PO in 3 doses × 7 d[83]	20 mg/kg/d PO in 3 doses × 7 d[83]

61. Although azole drugs (fluconazole, ketoconazole, itraconazole) have been used to treat cutaneous disease, they are not reliably effective and have very limited if any efficacy against mucosal disease (JA Blum and CS Hatz, J Travel Med 2009; 16:123). For treatment of *L. major* cutaneous lesions, a study in Saudi Arabia found that oral fluconazole, 200 mg once/d × 6 wks appeared to modestly accelerate the healing process (AA Alrajhi et al, N Engl J Med 2002; 346:891). Thermotherapy may be an option for some cases of cutaneous *L. tropica* infection (R Reithinger et al, Clin Infect Dis 2005; 40:1148). A device that generates focused and controlled heating of the skin is being marketed *(ThermoMed* - ThermoSurgery Technologies Inc., Phoenix, AZ, 602-264-7300; www.thermosurgery.com). In one small study after 12 months of followup localized thermal heat was as effective as 10 doses of sodium stibogluconate with less toxicity (NE Aronson et al, PLOS Negl Trop Dis 2010; 4:e628).
62. At this dosage pentamidine has been effective in Colombia predominantly against *L. (V.) panamensis* (J Soto-Mancipe et al, Clin Infect Dis 1993; 16:417; J Soto et al, Am J Trop Med Hyg 1994; 50:107). Activity against other species is not well established.
63. Mucosal infection (espundia) is most commonly due to New World species *L. (V.) braziliensis, L. (V.) panamensis,* or *L. (V.) guyanensis.*
64. Miltefosine has been effective for mucosal leishmania due to *L.(V.) braziliensis* in Bolivia (J Soto et al, Clin Infect Dis 2007; 44:350; J Soto et al, Am J Trop Med Hyg 2009; 81:387).
65. Pediculocides should not be used for infestations of the eyelashes. Such infestations are treated with petrolatum ointment applied 2-4x/d × 8-10 d. Oral TMP/SMX has also been used (TL Meinking and D Taplin, Curr Probl Dermatol 1996; 24:157). For pubic lice, treat with 5% permethrin or ivermectin as for scabies (see page 10). TMP/SMX has also been effective when used together with permethrin for head lice (RB Hipolito et al, Pediatrics 2001; 107:E30).
66. Permethrin and pyrethrin are pediculocidal; retreatment in 7-10 d is needed to eradicate the infestation. Some lice are resistant to pyrethrins and permethrin (TL Meinking et al, Arch Dermatol 2002; 138:220). Medical Letter consultants prefer pyrethrin products with a benzyl alcohol vehicle.
67. FDA-approved to treat head lice in 2009, benzyl alcohol prevents lice from closing their respiratory spiracles and the lotion vehicle then obstructs their airway causing them to asphyxiate. It is not ovicidal.Two applications at least 7 d apart are needed. Resistance, which is a problem with other drugs, is unlikely to develop (Med Lett Drugs Ther 2009; 51:57).
68. Malathion is both ovicidal and pediculocidal; 2 applications at least 7 d apart are generally necessary to kill all lice and nits.
69. Ivermectin is pediculocidal, but not ovicidal; more than one dose is generally necessary to eradicate the infestation (KN Jones and JC English 3rd, Clin Infect Dis 2003; 36:1355). The number of doses and interval between doses has not been established. In one study for treatment of head lice, 2 doses of ivermectin (400 mcg/kg) 7 days apart was more effective than treatment with topical malathion (O Chosidow et al, N Engl J Med 2010; 362:896). In one study for treatment of body lice, 3 doses of ivermectin (12 mg each) administered at 7 d intervals were effective (C Fouault et al, J Infect Dis 2006; 193:474).

Infection		Drug	Adult dosage	Pediatric dosage
Alternative:		Mefloquine[84,85]	750 mg PO followed 12 hrs later by 500 mg	15 mg/kg PO followed 12 hrs later by 10 mg/kg

				>40 kg: 4 adult tabs PO once/d × 3 d[77]
	OR	Quinine sulfate	650 mg PO q8h × 3-7 d[80]	30 mg/kg/d PO in 3 doses × 3-7 d[80]
		plus		
		doxycycline[7,20,81]	100 mg PO bid × 7 d	4 mg/kg/d PO in 2 doses × 7 d
	ALL PLUS	primaquine phosphate[75,87]	30 mg base/d PO × 14 d	0.5 mg/kg/d PO × 14 d

70. Chloroquine-resistant *P. falciparum* occurs in all malarious areas except Central America (including Panama north and west of the Canal Zone), Mexico, Haiti, the Dominican Republic, Paraguay, northern Argentina, North and South Korea, Georgia, Armenia, most of rural China and some countries in the Middle East (chloroquine resistance has been reported in Yemen, Saudi Arabia and Iran). For treatment of multiple-drug-resistant *P. falciparum* in Southeast Asia, especially Thailand, where mefloquine resistance is frequent, atovaquone/proguanil, quinine plus either doxycycline or clindamycin, or artemether/lumefantrine may be used.
71. *P. vivax* with decreased susceptibility to chloroquine is a significant problem in Papua-New Guinea and Indonesia. There are also reports of resistance from Myanmar, Vietnam, Korea, India, the Solomon Islands, Vanuatu, Indonesia, Guyana, Brazil, Colombia and Peru (JK Baird, Clin Microbiol Rev 2009; 22:508).
72. Chloroquine-resistant *P. malariae* has been reported from Sumatra (JD Maguire et al, Lancet 2002; 360:58).
73. Human infection with the simian species, *P. knowlesi* has been reported in Malaysia where it was initially misdiagnosed as *P. malariae*. Additional cases have been reported from Thailand, Myanmar, Singapore, the Thai-Burma border, and the Philippines (J Cox-Singh et al, Clin Infect Dis 2008; 46:165; MMWR 2009; 58:229). Treatment with the usual antimalarials, such as chloroquine and atovaquone/proguanil appear to be effective.
74. Uncomplicated or mild malaria may be treated with oral drugs. Severe malaria (e.g. impaired consciousness, parasitemia >5%, shock, etc.) should be treated with parenteral drugs (KS Griffin et al, JAMA 2007; 297:2264).
75. Primaquine is given as part of primary treatment to prevent relapse after infection with *P. vivax* or *P. ovale*. Some experts also prescribe primaquine phosphate 30 mg base/d (0.6 mg base/kg/d for children) for 14 d after departure from areas where these species are endemic (Presumptive Anti-Relapse Therapy [PART], "terminal prophylaxis"). Since this is not always effective as prophylaxis (E Schwartz et al, N Engl J Med 2003; 349:1510), others prefer to rely on surveillance to detect cases when they occur, particularly when exposure was limited or doubtful. See also footnote 87.
76. Atovaquone/proguanil is available as a fixed-dose combination tablet: adult tablets (*Malarone*; atovaquone 250 mg/proguanil 100 mg) and pediatric tablets (*Malarone Pediatric*; atovaquone 62.5 mg/proguanil 25 mg). To enhance absorption and reduce nausea and vomiting, it should be taken with food or a milky drink. Safety in pregnancy is unknown; in a few small studies; outcomes were normal in women treated with the combination in the 2nd and 3rd trimester (AK Boggild et al, Am J Trop Med Hyg 2007; 76:208). The drug should not be given to patients with severe renal impairment (creatinine clearance <30 mL/min). There have been isolated case reports of resistance in *P. falciparum* in Africa, but Medical Letter consultants do not believe there is a high risk for acquisition of *Malarone*-resistant disease (E Schwartz et al, Clin Infect Dis 2003; 37:450; A Farnert et al, BMJ 2003; 326:628; S Kuhn et al, Am J Trop Med Hyg 2005; 72:407; CT Happi et al, Malaria Journal 2006; 5:82).
77. Although approved for once-daily dosing, Medical Letter consultants usually divide the dose in two to decrease nausea and vomiting.

Infection		Drug	Adult dosage	Pediatric dosage
Alternative:		Mefloquine[84]	750 mg PO followed 12 hrs later by 500 mg	15 mg/kg PO followed 12 hrs later by 10 mg/kg
		Chloroquine phosphate[88,89]	25 mg base/kg PO in 3 doses over 48 hrs	25 mg base/kg PO in 3 doses over 48 hrs
		plus		
		doxycycline[7,20,81]	100 mg PO bid × 7 d	4 mg/kg/d PO in 2 doses × 7 d
	ALL PLUS	primaquine phosphate[75,87]	30 mg base/d PO × 14 d	0.5 mg/kg/d PO × 14 d
All *Plasmodium* species except chloroquine-resistant *P. falciparum*[70] and chloroquine-resistant *P. vivax*[71]				
Drug of choice:[75]		Chloroquine phosphate[88]	1 g (600 mg base) PO, then 500 mg (300 mg base) 6 hrs later, then 500 mg (300 mg base) at 24 and 48 hrs	10 mg base/kg (max. 600 mg base) PO, then 5 mg base/kg 6 hrs later, then 5 mg base/kg at 24 and 48 hrs
Parenteral (Severe infection)[74]				
All *Plasmodium* species (Chloroquine-sensitive and resistant)				
Drug of choice:[75,90]		Quinidine gluconate[91]	10 mg/kg IV loading dose (max. 600 mg) in normal saline over 1-2 hrs, followed by continuous infusion of 0.02 mg/kg/min until PO therapy can be started	10 mg/kg IV loading dose (max. 600 mg) in normal saline over 1-2 hrs, followed by continuous infusion of 0.02 mg/kg/min until PO therapy can be started
	OR	Quinine dihydrochloride[91*]	20 mg/kg IV loading dose in 5% dextrose over 4 hrs, followed by 10 mg/kg over 2-4 hrs q8h (max. 1800 mg/d) until PO therapy can be started	20 mg/kg IV loading dose in 5% dextrose over 4 hrs, followed by 10 mg/kg over 2-4 hrs q8h (max. 1800 mg/d) until PO therapy can be started
	OR	Artesunate[78*]	2.4 mg/kg/dose IV × 3 d at 0, 12, 24, 48 and 72 hrs	2.4 mg/kg/dose IV × 3 d at 0, 12, 24, 48 and 72 hrs
		plus see footnote 86		

78. The artemisinin-derivatives, artemether and artesunate, are both frequently used globally in combination regimens to treat malaria. Both are available in oral, parenteral and rectal formulations, but manufacturing standards are not consistent (HA Karunajeewa et al, JAMA 2007; 297:2381; EA Ashley and NJ White, Curr Opin Infect Dis 2005; 18:531). Oral artesunate is not available in the US; the IV formulation is available through the CDC Malaria branch (M-F, 8am-4:30pm ET, 770-488-7788, or after hours, 770-488-7100) under an IND for patients with severe disease who do not have timely access, cannot tolerate, or fail to respond to IV quinidine (Med Lett DrugsTher 2008; 50:37).To avoid development of resistance, monotherapy should be avoided (PE Duffy and CH Sibley, Lancet 2005; 366:1908). Reduced susceptibility to artesunate characterized by slow parasitic clearance has been reported in Cambodia (WO Rogers et al, Malaria J 2009; 8:10; AM Dundorp et al, N Engl J Med 2009; 361:455). Based on the few studies available, artemesin have been relatively safe during pregnancy (I Adam et al, Am Trop Med Parisito 2009; 103; 205), but some experts would not prescribe them in the 1st trimester (RL Clark, Reprod Toxicol 2009; 28:285).
79. Artemether/lumefantrine is available as a fixed-dose combination tablet (*Coartem* in the US and in countries with endemic malaria, *Riamet* in Europe and countries without endemic malaria); each tablet contains artemether 20 mg and lumefantrine 120 mg. It is FDA-approved for treatment of uncomplicated malaria and should not be used for severe infection or for prophylaxis. It is contraindicated during the 1st trimester of pregnancy; safety during the 2nd and 3rd trimester is not known. The tablets should be taken with fatty food (tablets may be crushed and mixed with 1-2 tsp water, and taken with milk). Artemether/lumefantrine should not be used in patients with cardiac arrhythmias, bradycardia, severe cardiac disease or QT prolongation. Concomitant use of drugs that prolong the QT interval or are metabolized by CYP2D6 is contraindicated (Med Lett Drugs Ther 2009; 51:75).
80. Available in the US in a 324-mg capsule; 2 capsules suffice for adult dosage. In Southeast Asia, relative resistance to quinine has increased and treatment should be continued for 7 d. Quinine should be taken with or after meals to decrease gastrointestinal adverse effects. It is generally considered safe in pregnancy.
81. Doxycycline should be taken with adequate water to avoid esophageal irritation. It can be taken with food to minimize gastrointestinal adverse effects.
82. For use in pregnancy and in children <8 yrs.
83. B Lell and PG Kremsner, Antimicrob Agents Chemother 2002; 46:2315; M Ramharter et al, Clin Infect Dis 2005; 40:1777.
84. At this dosage, adverse effects include nausea, vomiting, diarrhea and dizziness. Disturbed sense of balance, toxic psychosis and seizures can also occur. Mefloquine should not be used for treatment of malaria in pregnancy unless there is not another treatment option (F Nosten et al, Curr Drug Saf 2006; 1:1). It should be avoided for treatment of malaria in persons with active depression or with a history of psychosis or seizures and should be used with caution in persons with any psychiatric illness. Mefloquine should not be used in patients with conduction abnormalities; it can be given to patients taking β-blockers if they do not have an underlying arrhythmia. Mefloquine should not be given together with quinine or quinidine, and caution is required in using quinine or quinidine to treat patients with malaria who have taken mefloquine for prophylaxis. Mefloquine should not be taken on an empty stomach; it should be taken with at least 8 oz of water.

				>19-30 kg: ½ tab once/ wk[96]
				>31-45 kg: ¾ tab once/ wk[96]
				>45 kg: 1 tab once/wk[96]
Alternative:[97]		Primaquine[7,87] phosphate	30 mg base PO daily[98]	0.5 mg/kg base PO daily[98]
All Plasmodium species in chloroquine-sensitive areas[70-73]				
Drug of choice:[75,99]		Chloroquine phosphate[88,100]	500 mg (300 mg base) PO once/wk[101]	5 mg/kg base PO once/ wk, up to adult dose of 300 mg base[101]

85. *P. falciparum* with resistance to mefloquine is a significant problem in the malarious areas of Thailand and in areas of Myanmar and Cambodia that border on Thailand. It has also been reported on the borders between Myanmar and China, Laos and Myanmar, and in Southern Vietnam. In the US, a 250-mg tablet of mefloquine contains 228 mg mefloquine base. Outside the US, each 275-mg tablet contains 250 mg base.

86. Adults treated with artesunate should also receive oral treatment doses of either atovaquone/proguanil, doxycycline, clindamycin or mefloquine; children should take either atovaquone/proguanil, clindamycin or mefloquine (F Nosten et al, Lancet 2000; 356:297; M van Vugt, Clin Infect Dis 2002; 35:1498; F Smithuis et al, Trans R Soc Trop Med Hyg 2004; 98:182). If artesunate is given IV, oral medication should be started when the patient is able to tolerate it (SEAQUAMAT group, Lancet 2005; 366:717).

87. Primaquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in G-6-PD. This deficiency is most common in African, Asian and Mediterranean peoples. Patients should be screened for G-6-PD deficiency before treatment. Primaquine should not be used during pregnancy. It should be taken with food to minimize nausea and abdominal pain. Primaquine-tolerant *P. vivax* can be found globally. Relapses of primaquine-resistant strains may be retreated with 30 mg (base) × 28 d.

88. Chloroquine should be taken with food to decrease gastrointestinal adverse effects. If chloroquine phosphate is not available, hydroxychloroquine sulfate is as effective; 400 mg of hydroxychloroquine sulfate is equivalent to 500 mg of chloroquine phosphate.

89. Chloroquine combined with primaquine was effective in 85% of patients with *P. vivax* resistant to chloroquine and could be a reasonable choice in areas where other alternatives are not available (JK Baird et al, J Infect Dis 1995; 171:1678).

90. Exchange transfusion is controversial, but has been helpful for some patients with high-density (>10%) parasitemia, altered mental status, pulmonary edema or renal complications (PJ Van Genderen et al, Transfusion 2009; Nov 20 epub).

91. Continuous EKG, blood pressure and glucose monitoring are recommended. Quinine IV is not available in the US. Quinidine may have greater antimalarial activity than quinine. The loading dose should be decreased or omitted in patients who have received quinine or mefloquine. If more than 48 hours of parenteral treatment is required, the quinine or quinidine dose should be reduced by 30-50%. Intrarectal quinine has been tried for the treatment of cerebral malaria in children (J Achan et al, Clin Infect Dis 2007; 45:1446).

92. No drug guarantees protection against malaria. Travelers should be advised to seek medical attention if fever develops after they return. Insect repellents, insecticide-impregnated bed nets and proper clothing are important adjuncts for malaria prophylaxis (Treat Guidel Med Lett 2009; 7:83). Malaria in pregnancy is particularly serious for both mother and fetus; prophylaxis is indicated if exposure cannot be avoided.

93. Beginning 1-2 d before travel and continuing for the duration of stay and for 1 wk after leaving malarious zone. In one study of malaria prophylaxis, atovaquone/proguanil was better tolerated than mefloquine in nonimmune travelers (D Overbosch et al, Clin Infect Dis 2001; 33:1015). The protective efficacy of *Malarone* against *P. vivax* is variable ranging from 84% in Indonesian New Guinea (J Ling et al, Clin Infect Dis 2002; 35:825) to 100% in Colombia (J Soto et al, Am J Trop Med Hyg 2006; 75:430). Some Medical Letter consultants prefer alternate drugs if traveling to areas where *P. vivax* predominates.

Infection		Drug	Adult dosage	Pediatric dosage
Malaria, Prevention of relapses: *P. vivax* and *P. ovale*[75]				
Drug of choice:		Primaquine phosphate[87]	30 mg base/d PO × 14 d	0.5 mg base/kg/d PO × 14 d
Malaria, Self-Presumptive Treatment[102]				
Drug of Choice:		Atovaquone/ proguanil[7,76]	4 adult tabs once/d or 2 adult tabs bid × 3 d[77]	<5 kg: not indicated 5-8 kg: 2 peds tabs once/d × 3 d 9-10 kg: 3 peds tabs once/d × 3 d 11-20 kg: 1 adult tab once/d × 3 d 21-30 kg: 2 adult tabs once/d × 3 d 31-40 kg: 3 adult tabs once/d × 3 d >40 kg: 4 adult tabs once/d × 3 d[77]
	OR	Artemether/ lumefantrine[7,78,79]	6 doses over 3 d (4 tabs/ dose at 0, 8, 24, 36, 48 and 60 hours)	6 doses over 3 d at same intervals as adults; 5-15 kg: 1 tab/dose 15-25 kg: 2 tabs/dose 25-35 kg: 3 tabs/dose >35 kg: 4 tabs/dose
	OR	Quinine sulfate	650 mg PO q8h × 3 or 7 d[70]	30 mg/kg/d PO in 3 doses × 3 or 7 d[70]
		plus		
		doxycycline[7,20,81]	100 mg PO bid × 7 d	4 mg/kg/d PO in 2 doses × 7 d
	OR	Artesunate[78*]	4 mg/kg/d PO × 3 d	4 mg/kg/d PO ×3 d
		plus see footnote 86		
Microsporidiosis				
Ocular *(Encephalitozoon hellem, E. cuniculi, Vittaforma [Nosema] corneae)*				
Drug of choice:		Fumagillin[103*]		
		plus		
		albendazole[7,12]	400 mg PO bid	15 mg/kg/d in 2 doses (max 400 mg/dose)

94. Beginning 1-2 d before travel and continuing for the duration of stay and for 4 wks after leaving malarious zone. Doxycycline can cause gastrointestinal disturbances, vaginal moniliasis and photosensitivity reactions.
95. Mefloquine has not been approved for use during pregnancy. However, it has been reported to be safe for prophylactic use during the second and third trimester of pregnancy and possibly during early pregnancy as well (CDC Health Information for International Travel, 2010, page 141). Not recommended for use in travelers with active depression or with a history of psychosis or seizures and should be used with caution in persons with psychiatric illness. Mefloquine should not be used in patients with conduction abnormalities; it can be given to patients taking β-blockers if they do not have an underlying arrhythmia.
96. Beginning 1-2 wks before travel and continuing weekly for the duration of stay and for 4 wks after leaving malarious zone. Most adverse events occur within 3 doses. Some Medical Letter consultants favor starting mefloquine 3 weeks prior to travel and monitoring the patient for adverse events, this allows time to change to an alternative regimen if mefloquine is not tolerated. Mefloquine should not be taken on an empty stomach; it should be taken with at least 8 oz of water. For pediatric doses <½ tablet, it is advisable to have a pharmacist crush the tablet, estimate doses by weighing, and package them in gelatin capsules.There is no data for use in children <5 kg, but based on dosages in other weight groups, a dose of 5 mg/kg can be used.
97. The combination of weekly chloroquine (300 mg base) and daily proguanil (200 mg) is recommended by the World Health Organization (www.WHO.int) for use in selected areas; this combination is no longer recommended by the CDC. Proguanil (*Paludrine* – AstraZeneca, United Kingdom) is not available alone in the US but is widely available in Canada and Europe. Prophylaxis is recommended during exposure and for 4 weeks afterwards. Proguanil has been used in pregnancy without evidence of toxicity (PA Phillips-Howard and D Wood, Drug Saf 1996; 14:131).
98. Studies have shown that daily primaquine beginning 1 d before departure and continued until 3-7 d after leaving the malarious area provides effective prophylaxis against chloroquine-resistant *P. falciparum* (DR Hill et al, Am J Trop Med Hyg 2006; 75:402). Nausea and abdominal pain can be diminished by taking with food.
99. Alternatives for patients who are unable to take chloroquine include atovaquone/proguanil, mefloquine, doxycycline or primaquine dosed as for chloroquine-resistant areas.

Infection	Drug	Adult dosage	Pediatric dosage
Intestinal *(E. bieneusi, E. [Septata] intestinalis)*			
E. bieneusi			
Drug of choice:	Fumagillin[104*]	20 mg PO tid × 14 d	
E. intestinalis			
Drug of choice:	Albendazole[7,12]	400 mg PO bid × 21 d	15 mg/kg/d in 2 doses (max 400 mg/dose)
Disseminated *(E. hellem, E. cuniculi, E. intestinalis, Pleistophora sp., Trachipleistophora sp.* and Anncaliia *[Brachiola] vesicularum)*			
Drug of choice:[105]	Albendazole[7,12]	400 mg PO bid	15 mg/kg/d in 2 doses (max 400 mg/dose)
Mites, see SCABIES			
Moniliformis *moniliformis* infection			
Drug of choice:	Pyrantel pamoate[7,31*]	11 mg/kg PO once, repeat twice, 2 wks apart	11 mg/kg PO once, repeat twice, 2 wks apart
Naegleria **species,** see AMEBIC MENINGOENCEPHALITIS, PRIMARY			
Necator americanus, see HOOKWORM infection			
Oesophagostomum *bifurcum*			
Drug of choice:	See footnote 106		
Onchocerca volvulus, see FILARIASIS			
Opisthorchis viverrini, see FLUKE infection			
Paragonimus westermani, see FLUKE infection			
Pediculus capitis, humanus, Phthirus pubis, see LICE			
Pinworm, see ENTEROBIUS			
Pneumocystis Jirovecii (formerly *carinii*) pneumonia (PCP)[107]			
Moderate to Severe Disease[108]			
Drug of choice:	Trimethoprim/ sulfamethoxazole	TMP 15-20 mg/kg/d SMX 75-100 mg/kg/d PO or IV in 3 or 4 doses (change to PO after clinical improvement) × 21 d	TMP 15-20 mg/kg/d SMX 75-100 mg/kg/d PO or IV in 3 or 4 doses (change to PO after clinical improvement) × 21 d

100. Has been used extensively and safely for prophylaxis in pregnancy.
101. Beginning 1-2 wks before travel and continuing weekly for the duration of stay and for 4 wks after leaving malarious zone.
102. A traveler can be given a course of medication for presumptive self-treatment of febrile illness. The drug given for self-treatment should be different from that used for prophylaxis. This approach should be used only in very rare circumstances when a traveler would not be able to get medical care promptly.
103. CM Chan et al, Ophthalmology 2003; 110:1420. Ocular lesions due to *E. hellem* in HIV-infected patients have responded to fumagillin eyedrops prepared from *Fumidil-B* (bicyclohexyl ammonium fumagillin) used to control a microsporidial disease of honey bees (MJ Garvey et al, Ann Pharmacother 1995; 29:872), available from Leiter's Park Avenue Pharmacy (see footnote 1). For lesions due to *V. corneae*, topical therapy is generally not effective and keratoplasty may be required (RM Davis et al, Ophthalmology 1990; 97:953).
104. Oral fumagillin (*Flisint* – Sanofi-Aventis, France) has been effective in treating *E.* bieneusi in patients with HIV or solid organ transplants (J-M Molina et al, N Engl J Med 2002; 346:1963; F Lanternier et al, Transpl Infect Dis 2009; 11:83), but has been associated with thrombocytopenia and neutropenia. Potent anti retroviral therapy (ART) may lead to microbiologic and clinical response in HIV-infected patients with microsporidial diarrhea. Octreotide *(Sandostatin)* has provided symptomatic relief in some patients with large-volume diarrhea.
105. J-M Molina et al, J Infect Dis 1995; 171:245. There is no established treatment for *Pleistophora*. For disseminated disease due to *Trachipleistophora* or *Anncaliia*, itraconazole 400 mg PO once/d plus albendazole may also be tried (CM Coyle et al, N Engl J Med 2004; 351:42).
106. Albendazole or pyrantel pamoate may be effective (JB Ziem et al, Ann Trop Med Parasitol 2004; 98:385).

Infection		Drug	Adult dosage	Pediatric dosage
Alternative:		Pentamidine	3-4 mg/kg IV daily × 21 d	3-4 mg/kg IV daily × 21 d
	OR	Primaquine[7,87]	30 mg base PO daily × 21 d	0.3 mg/kg base PO (max. 30 mg) daily × 21 d
		plus		
		clindamycin[7,18]	600-900 mg IV tid or qid × 21 d, or 300-450 mg PO tid or qid × 21 d (change to PO after clinical improvement)	15-25 mg/kg IV tid or qid (max 600 mg/dose) × 21 d, or 10 mg/kg PO tid or qid (max 300-450 mg/dose) × 21 d (change to PO after clinical improvement)
Mild to Moderate Disease				
Drug of Choice:		Trimethoprim/ sulfamethoxazole	2 DS tablets (160 mg/800 mg) PO tid × 21 d	TMP 15-20 mg/kg/SMX 75-100 mg/kg/d PO in 3 or 4 doses × 21 d
Alternative:		Dapsone[7]	100 mg PO daily × 21 d	2 mg/kg/d (max. 100 mg) PO × 21 d
		plus		
		Trimethoprim[7]	15 mg/kg/d PO in 3 doses	15 mg/kg/d PO in 3 doses
	OR	Primaquine[7,87]	30 mg base PO daily × 21 d	0.3 mg/kg base PO daily (max. 30 mg) × 21 d
		plus		
		clindamycin[7,18]	300-450 mg PO tid or qid × 21 d	10 mg/kg PO tid or qid (max 300-450 mg/dose) × 21 d
	OR	Atovaquone17	750 mg PO bid × 21 d	1-3 mos: 30 mg/kg/d PO × 21 d 4-24 mos: 45 mg/kg/d PO × 21 d >24 mos: 30 mg/kg/d PO × 21 d
Primary and Secondary Prophylaxis[109]				
Drug of Choice:		Trimethoprim/ sulfamethox-azole	1 tab (SS or DS) daily or 1 DS tab PO 3 d/wk	TMP 150 mg/SMX 750 mg/m^2/d PO in 2 doses 3 d/wk
Alternative:		Dapsone[7]	50 mg PO bid or 100 mg PO daily	> 1 mos: 2 mg/kg/d (max. 100 mg) PO or 4 mg/kg (max. 200 mg) PO each wk
	OR	Dapsone[7]	50 mg PO daily or 200 mg PO each wk	
		plus pyrimeth-amine[110]	50 mg PO daily or 75 mg PO each wk	
	OR	Atovaquone[7,17]	1500 mg/d PO in 1 or 2 doses	1-3 mos: 30 mg/kg/d PO 4-24 mos: 45 mg/kg/d PO >24 mos: 30 mg/kg/d PO
	OR	Pentamidine	300 mg aerosol inhaled monthly via *Respirgard II* nebulizer	≥5 yrs: 300 mg inhaled monthly via *Respirgard II* nebulizer

107. Pneumocystis has been reclassified as a fungus.
108. In severe disease with room air $PO_2 \leq 70$ mmHg or Aa gradient ≥ 35 mmHg, prednisone or its IV equivalent should also be used. For adults: d 1-5: 40 mg PO bid; d 6-10: 40 mg PO daily; d 11-21: 20 mg PO daily. For children: d 1-5: 2 mg/kg/d PO in 2 doses; d 6-10: 1 mg/kg/d PO in 2 doses; d 11-21: 0.5 mg/kg/d PO daily (JE Kaplan et al, Morbid Mortal Wkly Rep 2009; 58(RR04):1; Morbid Mortal Wkly Rep 2009; 58(RR11):1).
109. Primary/secondary prophylaxis in patients with HIV can be discontinued after CD4 count increases to >200 × 10^6/L for >3 mos.
110. Plus leucovorin 25 mg with each dose of pyrimethamine. Pyrimethamine should be taken with food to minimize gastrointestinal adverse effects.

Infection	Drug	Adult dosage	Pediatric dosage
River Blindness, see FILARIASIS			
Roundworm, see ASCARIASIS			
Sappinia Diploidea, See AMEBIC MENINGOENCEPHALITIS, PRIMARY			
Sarcocystis spp. (intestinal and muscular), see footnote 111			
Scabies *(Sarcoptes scabiei)*[112]			
Drug of choice:	5% Permethrin	Topically, 2× at least 7 d apart	Topically, 2× at least 7 d apart
Alternative:[113]	Ivermectin[7,15]	200 mcg/kg PO 2× at least 7 d apart[114]	200 mcg/kg PO, 2× at least 7 d apart[114]
	10% Crotamiton	Topically overnight on days 1, 2, 3, 8	Topically overnight on days 1, 2, 3, 8
Schistosomiasis *(Bilharziasis)*			
S. haematobium			
Drug of choice:	Praziquantel[44,115]	40 mg/kg/d PO in 1 or 2 doses × 1 d	40 mg/kg/d PO in 2 doses × 1 d
S. intercalatum[116]			
Drug of Choice:	Praziquantel[44,115]	40 mg/kg/d PO in 1 or 2 doses × 1 d	40 mg/kg/d PO × 1 d
S. japonicum			
Drug of choice:	Praziquantel[44,115]	60 mg/kg/d PO in 2 or 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d
S. mansoni			
Drug of choice:	Praziquantel[44,115]	40 mg/kg/d PO in 1 or 2 doses × 1 d	40 mg/kg/d PO in 2 doses × 1 d
Alternative:	Oxamniquine[117*]	15 mg/kg PO once[118]	20 mg/kg/d PO in 2 doses × 1 d[118]
S. mekongi			
Drug of choice:	Praziquantel[44,115]	60 mg/kg/d PO in 2 or 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d
Sleeping Sickness, see TRYPANOSOMIASIS			
Strongyloidiasis *(Strongyloides stercoralis)*			
Drug of choice:[119]	Ivermectin[15]	200 mcg/kg/d PO × 2 d	200 mcg/kg/d PO × 2 d
Alternative:	Albendazole[7,12]	400 mg PO bid × 7 d	400 mg PO bid × 7 d
Tapeworm infection — ADULT (intestinal stage) *DIPHYLLOBOTHRIUM LATUM* (FISH), *TAENIA SAGINATA* (BEEF), *TAENIA SOLIUM* (PORK), *DIPYLIDIUM CANINUM* (DOG)			
Drug of choice:	Praziquantel[7,44]	5-10 mg/kg PO once	5-10 mg/kg PO once
Alternative:	Niclosamide[120*]	2 g PO once	50 mg/kg PO once

111. Sarcocystis in humans is acquired by ingesting sporocysts in infected meat, infections characterized by nausea, abdominal pain and diarrhea. Muscular infections are usually mild or subclinical (R Fayer, Clin Microbiol Rev 2004; 17:894). Albendazole was reported to be efficacious (MK Arness et al, Am J Trop Med Hyg 1999; 61:548).
112. TL Meinking et al, Infestations in LA Schachner and RA Hansen, eds. *Pediatric Dermatology*. 3rd ed. St Louis: Mosby; 2003, page 1291.
113. Lindane (γ-benzene hexachloride) should be reserved for treatment of patients who fail to respond to other drugs. The FDA has recommended it not be used for immunocompromised patients, young children, the elderly, pregnant and breast-feeding women, and patients weighing <50 kg.
114. BJ Currie and JS McCarthy, N Engl J Med 2010; 362:717. A second ivermectin dose taken 2 weeks later increased the cure rate to 95%, which is equivalent to that of 5% permethrin (V Usha et al, J Am Acad Dermatol 2000; 42:236). Ivermectin, either alone or in combination with a topical scabicide, is the drug of choice for crusted scabies in immunocompromised patients (P del Giudice, Curr Opin Infect Dis 2004; 15:123).
115. MJ Doenhoff et al, Curr Opin Infect Dis 2008; 21:659.
116. Geographically restricted to Central Western Africa and the island of São Tomé. Usually a disease of the lower GI tract; there are also case reports of complications including central nervous system, liver and cardiopulmonary involvement (A Murinello et al, GE—J Port Gastrenterol 2006; 13:97).

Infection	Drug	Adult dosage	Pediatric dosage
***HYMENOLEPIS NANA* (DWARF TAPEWORM)**			
Drug of choice:	Praziquantel[7,44]	25 mg/kg PO once	25 mg/kg PO once
Alternative:[121]	Niclosamide[120*]	2 g PO daily × 7 d	11-34 kg: 1 g PO on d 1 then 500 mg/d PO × 6 days > 34 kg: 1.5 g PO on d 1 then 1 g/d PO × 6 days
— LARVAL (tissue stage)			
***ECHINOCOCCUS GRANULOSUS* (hydatid cyst)**			
Drug of choice:[122]	Albendazole[12]	400 mg PO bid × 1-6 mos	15 mg/kg/d (max. 800 mg) PO in 2 doses × 1-6 mos
ECHINOCOCCUS MULTILOCULARIS			
Treatment of choice:	See footnote 123		
Taenia solium (Cysticercosis)			
Treatment of choice:	See footnote 124		
Alternative:	Albendazole[12]	400 mg PO bid × 8-30 d; can be repeated as necessary	15 mg/kg/d (max. 800 mg) PO in 2 doses × 8-30 d; can be repeated as necessary
OR	Praziquantel[7,44]	100 mg/kg/d PO in 3 doses × 1 day then 50 mg/kg/d in 3 doses × 29 days	100 mg/kg/d PO in 3 doses × 1 day then 50 mg/kg/d in 3 doses × 29 days
Toxocariasis, see VISCERAL LARVA MIGRANS			
Toxoplasmosis *(Toxoplasma gondii)*			
***CNS Disease*[125]**			
Drug of choice:	Pyrimethamine[126]	200 mg PO × 1 then 50-75 mg/d PO × 3-6 wks	2 mg/kg/d PO × 2 d, then 1 mg/kg/d (max. 25 mg/d) × 3-6 wks
	plus		
	sulfadiazine[127]	1-1.5 g PO qid × 3-6 wks	100-200 mg/kg/d PO × 3-6 wks
OR	**plus**		

117. Oxamniquine, which is not available in the US, is generally not as effective as praziquantel. It has been useful, however, in some areas in which praziquantel is less effective (ML Ferrari et al, Bull World Health Organ 2003; 81:190; A Harder, Parasitol Res 2002; 88:395). Oxamniquine is contraindicated in pregnancy. It should be taken after food.
118. In East Africa, the dose should be increased to 30 mg/kg PO, and in Egypt and South Africa to 30 mg/kg/d PO × 2 d. Some experts recommend 40-60 mg/kg PO over 2-3 d in all of Africa (KC Shekhar, Drugs 1991; 42:379).
119. In immunocompromised patients or disseminated disease, it may be necessary to prolong or repeat therapy, or to use other agents. Veterinary parenteral and enema formulations of ivermectin have been used in severely ill patients with hyperinfection who were unable to take or reliably absorb oral medications (FM Marty et al, Clin Infect Dis 2005; 41:e5; P Lichtenberger et al, Transpl Infect Dis 2009; 11:137). In disseminated strongyloidiasis, combination therapy with albendazole and ivermectin has been suggested (M Seqarra, Ann Pharmacother 2007; 41:1992).
120. Niclosamide must be thoroughly chewed or crushed and swallowed with a small amount of water.
121. Nitazoxanide may be an alternative (JJ Ortiz et al, Trans R Soc Trop Med Hyg 2002; 96:193; JC Chero et al, Trans R Soc Trop Med Hyg 2007; 101:203; E Diaz et al, Am J Trop Med Hyg 2003; 68:384).
122. Patients may benefit from surgical resection or percutaneous drainage of cysts. Praziquantel is useful preoperatively or in case of spillage of cyst contents during surgery. Percutaneous aspiration-injection-reaspiration (PAIR) with ultrasound guidance plus albendazole therapy has been effective for management of hepatic hydatid cyst disease (P Moro and PM Schantz, Int J Infect Dis 2009; 13:125.).
123. Surgical excision is the only reliable means of cure. Reports have suggested that in nonresectable cases use of albendazole (400 mg bid) can stabilize and sometimes cure infection (P Moro and PM Schantz, Int J Infect Dis 2009; 13:125).
124. Advances in neuroimaging using CT and MRI have facilitated the ability to make an accurate diagnosis (AC White Jr, J Infect Dis 2009; 199:1261). Initial therapy for patients with inflamed parenchymal cysticercosis should focus on symptomatic treatment with anti-seizure medication (S Sinha and BS Sharma, J Clin Neurosci 2009; 16:867). Patients with live parenchymal cysts who have seizures should be treated with albendazole together with steroids and an anti-seizure medication (HH Garcia et al, N Engl J Med 2004; 350:249). Patients with subarachnoid cysts or giant cysts in the fissures should be treated for at least 30 d (JV Proaño et al, N Engl J Med 2001; 345:879). Surgical intervention (especially neuroendoscopic removal) or CSF diversion followed by albendazole and steroids is indicated for obstructive hydocephalus. Arachnoiditis, vasculitis or cerebral edema is treated with albendazole or praziquantel plus prednisone (60 mg/d) or dexamethasone (4-6 mg/d). Any cysticercocidal drug may cause irreparable damage when used to treat ocular or spinal cysts, even when corticosteroids are used. An ophthalmic exam should always precede treatment to rule out intraocular cysts.

Infection		Drug	Adult dosage	Pediatric dosage
		clindamycin[7,128]	1.8-2.4 g/d IV or PO in 3 or 4 doses	5-7.5 mg/kg/d IV or PO in 3 or 4 doses (max 600 mg/dose)
	OR	**plus**		
		atovaquone[7,17,128]	1500 mg PO bid	1500 mg PO bid
Alternative:		Trimethoprim/ sulfamethoxazole[7]	15-20 mg/kg/SMX 75-100 mg/kg/d PO or IV in 3 or 4 doses	15-20 mg/kg/SMX 75-100 mg/kg/d PO or IV in 3 or 4 doses
Primary Infection in Pregnancy				
Treatment of choice:		See footnote 129		
Trichinellosis *(Trichinella spiralis)*				
Drug of choice:[130]		Steroids for severe symptoms, e.g.	prednisone 30-60 mg PO daily ×10-15 d	
		plus		
		Albendazole[7,12]	400 mg PO bid × 8-14 d	400 mg PO bid × 8-14 d
Alternative:		Mebendazole[7]	200-400 mg PO tid × 3 d, then 400-500 mg tid × 10 d	200-400 mg PO tid × 3 d, then 400-500 mg tid × 10 d
Trichomoniasis *(Trichomonas vaginalis)*				
Drug of choice:[131]		Metronidazole	2 g PO once	15 mg/kg/d PO in 3 doses × 7 d
	OR	Tinidazole[6]	2 g PO once	50 mg/kg once (max. 2 g)
Trichostrongylus infection				
Drug of choice:		Pyrantel pamoate[7,31*]	11 mg/kg base PO once (max. 1 g)	11 mg/kg PO once (max. 1 g)
Alternative:		Mebendazole[7]	100 mg PO bid × 3 d	100 mg PO bid × 3 d
	OR	Albendazole[7,12]	400 mg PO once	400 mg PO once
Trichuriasis (*Trichuris trichiura*, whipworm)				
Drug of choice:		Albendazole[7,12]	400 mg PO × 3 d	400 mg PO × 3 d
Alternative:		Mebendazole	100 mg PO bid × 3 d	100 mg PO bid × 3 d
	OR	Ivermectin[7,15]	200 mcg/kg/d PO × 3 d	200 mcg/kg/d PO × 3 d
Trypanosomiasis				
T. cruzi (American trypanosomiasis, Chagas' disease)[132]				
Drug of choice:		Nifurtimox*	8-10 mg/kg/d PO in 3-4 doses × 90-120 d	1-10 yrs: 15-20 mg/kg/d PO in 4 doses × 90-120 d 11-16 yrs: 12.5-15 mg/kg/d PO in 4 doses × 90-120 d
	OR	Benznidazole[133*]	5-7 mg/kg/d PO in 2 doses × 60-90 d	≤12 yrs: 10 mg/kg/d PO in 2 doses × 60-90 d >12 yrs: 5-7 mg/kg/d PO in 2 doses × 60-90 d

125. Treatment is followed by chronic suppression with lower dosage regimens of the same drugs. For primary prophylaxis in HIV patients with CD4 <100 × 10^6 cells/L, either trimethoprim-sulfamethoxazole, pyrimethamine with dapsone, or atovaquone with or without pyrimethamine can be used. Primary or secondary prophylaxis may be discontinued when the CD4 count increases to >200 × 10^6 cells/L for >3 mos (MMWR Morb Mortal Wkly Rep 2009; 58 [RR4]:1). In ocular toxoplasmosis with macular involvement, corticosteroids are recommended in addition to antiparasitic therapy (JG Montoya and O Liesenfeld, Lancet 2004; 363:1965).

126. Plus leucovorin 10-25 mg with each dose of pyrimethamine. Pyrimethamine should be taken with food to minimize gastrointestinal adverse effects.

127. Sulfadiazine should be taken on an empty stomach with adequate water.

128. Clindamycin has been used in combination with pyrimethamine to treat CNS toxoplasmosis in HIV infected patients who developed sulfonamide sensitivity while on sulfadiazine (G Beraud et al, Am J Trop Med Hygiene 2009; 80:583). Atovaquone has also been used to treat sulfonamide-intolerant patients (K Chirgwin et al, Clin Infect Dis 2002; 34:1243).

129. Women who develop toxoplasmosis during the first trimester of pregnancy should be treated with spiramycin (3-4 g/d). After the first trimester, if there is no documented transmission to the fetus, spiramycin can be continued until term. Spiramycin is not currently available in the US but can be obtained at no cost from Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL, 650-853-4828), US National Collaborative Treatment Trials Study (773-834-4152), or the FDA (301-796-1600). If transmission has occurred *in utero*, therapy with pyrimethamine and sulfadiazine should be started. Pyrimethamine is a potential teratogen and should be used only after the first trimester (JG Montoya and JS Remington, Clin Infect Dis 2008; 47:554). Congenitally infected new borns should be treated with pyrimethamine every 2 or 3 days and a sulfonamide daily for about one year (JS Remington and G Desmonts in JS Remington and JO Klein, eds, *Infectious Disease of the Fetus and Newborn Infant*, 6th ed, Philadelphia:Saunders, 2006, page 1038).

Infection		Drug	Adult dosage	Pediatric dosage
T. brucei gambiense (West African trypanosomiasis, sleeping sickness)[134]				
HEMOLYMPHATIC STAGE				
Drug of choice:[135]		Pentamidine[7]	4 mg/kg/d IM × 7 d	4 mg/kg/d IM × 7 d
Alternative:		Suramin*	100-200 mg (test dose) IV, then 1 g IV on days 1,3,7,14 and 21	20 mg/kg on d 1,3,7,14 and 21
LATE DISEASE WITH CNS INVOLVEMENT				
Drug of Choice:[136]		Eflornithine[137]*	400 mg/kg/d IV in 4 doses × 14 d	400 mg/kg/d IV in 4 doses × 14 d
	OR	Eflornithine[137]*	400 mg/kg IV in 2 doses × 7 d	
		plus		
		Nitfurtimox	15 mg/kg/d PO in 3 doses × 10 d	
	OR	Melarsoprol[138]	2.2 mg/kg/d IV × 10 d	2.2 mg/kg/d IV × 10 d
T. b. rhodesiense (East African trypanosomiasis, sleeping sickness)[134]				
HEMOLYMPHATIC STAGE				
Drug of choice:		Suramin*	100-200 mg (test dose) IV, then 1 g IV on days 1,3,7,14 and 21	20 mg/kg IV on d 1,3,7,14 and 21
LATE DISEASE WITH CNS INVOLVEMENT				
Drug of choice:		Melarsoprol[138]	2-3.6 mg/kg/d IV × 3 d; after 7 d 3.6 mg/kg/d × 3 d; repeat again after 7 d	2-3.6 mg/kg/d IV × 3 d; after 7 d 3.6 mg/kg/d × 3 d; repeat again after 7 d
Visceral Larva Migrans[139] *(Toxocariasis)*		Albendazole[7,12]	400 mg PO bid × 5 d	400 mg PO bid × 5 d
Drug of choice:	OR	Mebendazole[7]	100-200 mg PO bid × 5 d	100-200 mg PO bid × 5 d
Whipworm, see TRICHURIASIS				
Wuchereria bancrofti, see FILARIASIS				

130. B Gottstein et al. Clin Microbiol Rev 2009; 22:127.
131. Sexual partners should be treated simultaneously with same dosage. If treatment failure occurs and reinfection is excluded, treat with metronidazole 500 mg PO bid ×7 d, or tinidazole 2 g PO once (MMWR Morb Mortal Wkly Rep 2006; 55 [RR11]:1).
132. Treatment of chronic or indeterminate Chagas' disease with benznidazole has been associated with reduced progression and increased negative seroconversion (C Bern et al, JAMA 2007; 298:2171; JA Perez-Molina et al, J Antimicrob Chemother 2009; 64:1139).
133. Benznidazole should be taken with meals to minimize gastrointestinal adverse effects. It is contraindicated during pregnancy.
134. PG Kennedy, Ann Neurol 2008; 64:116.
135. Pentamidine and suramin have equal efficacy, but pentamidine is better tolerated.
136. In one study eflornithine for 7 days combined with nifurtimox × 10 d was more effective and less toxic than eflornithine × 14 d (G Priotto et al, Lancet 2009;374:56).
137. Eflornithine is highly effective in *T.b. gambiense*, but not in *T.b. rhodesiense* infections. In one study of treatment of CNS disease due to *T.b. gambiense*, there were fewer serious complications with eflornithine than with melarsoprol (PG Kennedy, Ann Neurol 2008; 64:116). Eflornithine is available in limited supply only from the WHO. It is contraindicated during pregnancy.
138. E Schmid et al, J Infect Dis 2005; 191:1922. Corticosteroids have been used to prevent arsenical encephalopathy (J Pepin et al, Trans R Soc Trop Med Hyg 1995;89:92). Up to 20% of patients with *T.b.gambiense* fail to respond to melarsoprol (MP Barrett, Lancet 1999; 353:1113). In one study, a combination of low-dose melarsoprol (1.2 mg/kg/d IV) and nifurtimox (7.5 mg/kg PO bid) × 10 d was more effective than standard-dose melarsoprol alone (S Bisser et al, J Infect Dis 2007; 195:322).
139. Optimum duration of therapy is not known; some Medical Letter consultants would treat × 20 d. For severe symptoms or eye involvement, corticosteroids can be used in addition (D Despommier, Clin Microbiol Rev 2003; 16:265).

PRINCIPAL ADVERSE EFFECTS OF ANTIPARASITIC DRUGS

Adverse effects of antiparasitic drugs vary with dosage, duration of administration, concomitant therapy, renal and hepatic function, immune competence, and the age of the patient. The principal adverse effects of antiparasitic agents are listed in the following table. The designation of adverse effects as "frequent," "occasional" or "rare" is based on published reports and on the experience of Medical Letter consultants. Information about adverse interactions between drugs, including probable mechanisms and recommendations for clinical management, are available in the Medical Letter Adverse Drug Interactions Program.

ALBENDAZOLE *(ALBENZA)*

Occasional: abdominal pain; reversible alopecia; increased serum transaminases
Rare: leukopenia; rash; renal toxicity

AMPHOTERICIN B DEOXYCHOLATE (*FUNGIZONE*, AND OTHERS)

Frequent: renal damage; hypokalemia; thrombophlebitis at site of peripheral vein infusion; anorexia; headache; nausea; weight loss; bone marrow suppression with reversible decline in hematocrit; chills, fever, vomiting during infusion, possibly with delirium, hypotension or hypertension, wheezing, and hypoxemia, especially in cardiac or pulmonary disease
Occasional: hypomagnesemia; normocytic, normochromic anemia
Rare: hemorrhagic gastroenteritis; blood dyscrasias; rash; blurred vision; peripheral neuropathy; convulsions; anaphylaxis; arrhythmias; acute liver failure; reversible nephrogenic diabetes insipidus; hearing loss; acute pulmonary edema; spinal cord damage with intrathecal use

AMPHOTERICIN B LIPID FORMULATIONS *(AMBISONE, ABELCET, AMPHOTEC)*

Similar to amphotericin B but generally better tolerated. Nephrotoxicity is less common and less severe with the lipid-based formulations. Acute infusion reactions are worse with *Amphotec*, less with *Abelcet* and least with *AmBisome*. Liver toxicity has been reported.

ARTEMETHER *(ARTENAM)*

Occasional: neurological toxicity; possible increase in length of coma; increased convulsions; prolongation of QTc interval

ARTEMETHER/LUMEFANTRINE *(COATEM, RIAMET)*

Frequent: abdominal pain; anorexia; headache; dizziness; diarrhea; vomiting; nausea; palpitations; arthralgia; myalgia; asthenia; fatigue; pruritus; rash; sleep disorder; cough
Occasional: somnolence; involuntary muscle contractions; paresthesia; hypoesthesia; abnormal gait; ataxia
Rare: Hypersensitivity

ARTESUNATE

Occasional: ataxia; slurred speech; neurological toxicity; possible increase in length of coma; increased convulsions; prolongation of QTc interval

ATOVAQUONE (*MEPRON*, *MALARONE* [WITH *PROGUANIL*])

Frequent: rash; nausea
Occasional: diarrhea; increased amino-transferases; cholestasis

AZITHROMYCIN (*ZITHROMAX*, AND OTHERS)

Occasional: nausea; diarrhea; abdominal pain; headache; dizziness; vaginitis
Rare: angioedema; cholestatic jaundice; photosensitivity; reversible dose-related hearing loss

BENZNIDAZOLE *(ROCHAGAN)*

Frequent: allergic rash; dose-dependent polyneuropathy; GI disturbance; psychic disturbances

BENZYL ALCOHOL *(ULESFIA LOTION)*

Frequent: eye irritation; contact dermatitis

BITHIONOL *(BITIN)*

Frequent: photosensitivity reactions; vomiting; diarrhea; abdominal pain; urticaria
Rare: leukopenia; toxic hepatitis

CHLOROQUINE HCL and CHLOROQUINE PHOSPHATE (*ARALEN*, AND OTHERS)

Occasional: pruritus; vomiting; headache; confusion; depigmentation of hair; skin eruptions; corneal opacity; weight loss; partial alopecia; extraocular muscle palsies; exacerbation of psoriasis, eczema, and other exfoliative dermatoses; myalgias; photophobia
Rare: irreversible retinal injury (especially when total dosage exceeds 100 grams); discoloration of nails and mucus membranes; nerve-type deafness; peripheral neuropathy and myopathy; heart block; blood dyscrasias; hematemesis

CLARITHROMYCIN (*BIAXIN*, AND OTHERS)

Occasional: nausea; diarrhea; abdominal pain; abnormal taste; headache; dizziness
Rare: reversible dose-related hearing loss; pseudomembranous colitis; pancreatitis; torsades de pointes

CLINDAMYCIN (*CLEOCIN*, AND OTHERS)

Frequent: diarrhea; allergic reactions
Occasional: pseudomembranous colitis, sometimes severe, can occur even with topical use
Rare: blood dyscrasias; esophageal ulceration; hepatotoxicity; arrhythmia due to QTc prolongation

CROTAMITON *(EURAX)*

Occasional: rash

DAPSONE

Frequent: rash; transient headache; GI irritation; anorexia; infectious mononucleosis-like syndrome
Occasional: cyanosis due to methemoglobinemia and sulfhemoglobinemia; other blood dyscrasias, including hemolytic anemia; nephrotic syndrome; liver damage; peripheral neuropathy; hypersensitivity reactions; increased risk of lepra reactions; insomnia; irritability; uncoordinated speech; agitation; acute psychosis
Rare: renal papillary necrosis; severe hypoalbuminemia; epidermal necrolysis; optic atrophy; agranulocytosis; neonatal hyperbilirubinemia after use in pregnancy

DIETHYLCARBAMAZINE CITRATE *(HETRAZAN)*

Frequent: allergic or febrile reactions, which may be severe, in patients with microfilaria in the blood or the skin; GI disturbance
Rare: encephalopathy

DILOXANIDE FUROATE *(FURAMIDE)*

Frequent: flatulence
Occasional: nausea; vomiting; diarrhea
Rare: diplopia; dizziness; urticaria; pruritus

EFLORNITHINE (DIFLUOROMETHYLORNITHINE, DFMO, *ORNIDYL)*

Frequent: anemia; leukopenia
Occasional: diarrhea; thrombocytopenia; seizures
Rare: hearing loss

FLUCONAZOLE (*DIFLUCAN*, AND OTHERS)

Occasional: nausea; vomiting; diarrhea; abdominal pain; headache; rash; increased aminotransferases
Rare: severe hepatic toxicity; exfoliative dermatitis; anaphylaxis; Stevens-Johnson syndrome; toxic epidermal necrolysis; hair loss

FLUCYTOSINE *(ANCOBON)*

Frequent: blood dyscrasias, including pancytopenia and fatal agranulocytosis; GI disturbance, including severe diarrhea and ulcerative colitis; rash; hepatic dysfunction
Occasional: confusion; hallucinations
Rare: anaphylaxis

FURAZOLIDONE *(FUROXONE)*

Frequent: nausea; vomiting
Occasional: allergic reactions, including pulmonary infiltration; hypotension; urticaria; fever; vesicular rash; hypoglycemia; headache
Rare: hemolytic anemia in G-6-PD deficiency and neonates; disulfiram-like reaction with alcohol; MAO-inhibitor interactions; polyneuritis

IODOQUINOL (*YODOXIN*, AND OTHERS)

Occasional: rash; acne; slight enlargement of the thyroid gland; nausea; diarrhea; cramps; anal pruritus

Rare: optic neuritis, atrophy and loss of vision; peripheral neuropathy after prolonged use in high dosage (for months); iodine sensitivity

ITRACONAZOLE (*SPORANOX*, AND OTHERS)

Occasional: nausea; epigastric pain; headache; dizziness; edema; hypokalemia; rash; hepatic toxicity
Rare: congestive heart failure

IVERMECTIN *(STROMECTOL)*

Occasional: Mazzotti-type reaction seen in onchocerciasis, including fever; pruritus; tender lymph nodes; headache; and joint and bone pain
Rare: hypotension

KETOCONAZOLE (*NIZORAL*, AND OTHERS)

Frequent: nausea; vomiting
Occasional: decreased testosterone synthesis; gynecomastia; oligospermia and impotence in men; abdomina pain; rash; hepatitis; pruritus; dizziness; constipation; diarrhea; fever and chills; photophobia; headache
Rare: fatal hepatic necrosis; liver injury with jaundice; transient elevated transaminase; severe epigastric burning and pain; may interfere with adrenal function; anaphylaxis

MALATHION *(OVIDE)*

Occasional: local irritation

MEBENDAZOLE *(VERMOX)*

Occasional: diarrhea; abdominal pain
Rare: leukopenia; agranulocytosis; hypospermia

MEFLOQUINE *(LARIAM)*

Frequent: vertigo; lightheadedness; nausea; other GI disturbances; nightmares; visual disturbances; headache; insomnia
Occasional: confusion
Rare: psychosis; hypotension; convulsions; coma; paresthesias

MEGLUMINE ANTIMONIATE *(GLUCANTIME)*

— Similar to sodium stibogluconate

MELARSOPROL *(MEL B)*

Frequent: myocardial damage; albuminuria; hypertension; colic; Herxheimer-type reaction; encephalopathy; vomiting; peripheral neuropathy
Rare: shock

METRONIDAZOLE (*FLAGYL*, AND OTHERS)

Frequent: nausea; headache; anorexia; metallic taste
Occasional: vomiting; diarrhea; insomnia; weakness; dry mouth; stomatitis; vertigo; tinnitus; paresthesias; rash; dark urine; urethral burning; disulfiram-like reaction with alcohol; candidiasis
Rare: pseudomembranous colitis; leukopenia; pancreatitis; seizures; peripheral neuropathy; encephalopathy; cerebellar syndrome with ataxia, dysarthria and MRI abnormalities

MICONAZOLE *(MONISTAT I.V.)*

Occasional: phlebitis; thrombocytosis; chills; intense, persistent pruritus; rash; vomiting; hyperlipidemia; dizziness; blurred vision; local burning and irritation with topical use
Rare: anemia; thrombocytopenia; hyponatremia; renal insufficiency; anaphylaxis; cardiac and respiratory arrest with initial dose

MILTEFOSINE *(IMPAVIDO)*

Frequent: nausea; vomiting; diarrhea; motion sickness; increased creatinine

NICLOSAMIDE *(NICLOCIDE)*

Occasional: nausea; abdominal pain

NITAZOXANIDE *(ALINIA)*

Occasional: GI disturbance; headache
Rare: yellow discoloration of sclera; allergic reactions; increased creatinine; dizziness; flatulence; malaise; salivary gland enlargement; discolored urine; anemia; leukoytosis

ORNIDAZOLE *(TIBERAL)*

Occasional: dizziness; headache; GI disturbance
Rare: reversible peripheral neuropathy

OXAMNIQUINE *(VANSIL)*

Occasional: headache; fever; dizziness; somnolence and insomnia; nausea; diarrhea; rash; increased aminotransferases; ECG changes; EEG changes; orange-red discoloration of urine
Rare: seizures; neuropsychiatric disturbances

PAROMOMYCIN (AMINOSIDINE; *HUMATIN*)

Frequent: GI disturbance with oral use
Rare: eighth-nerve damage (mainly auditory) and renal damage when aminosidine is given IV; vertigo; pancreatitis

PENTAMIDINE ISETHIONATE (*PENTAM 300*, *NEBUPENT*, AND OTHERS)

Frequent: hypotension; hypoglycemia often followed by diabetes mellitus; vomiting; blood dyscrasias; renal damage; pain at injection site; GI disturbance
Occasional: may aggravate diabetes; shock; hypocalcemia; liver damage; cardiotoxicity; delirium; rash
Rare: Herxheimer-type reaction; anaphylaxis; acute pancreatitis; hyperkalemia

PERMETHRIN (*NIX*, AND OTHERS)

Occasional: burning; stinging; numbness; increased pruritus; pain; edema; erythema; rash

PRAZIQUANTEL (BILTRICIDE)

Frequent: abdominal pain; diarrhea; malaise; headache; dizziness
Occasional: sedation; fever; sweating; nausea; eosinophilia
Rare: pruritus; rash; edema; hiccups

PRIMAQUINE PHOSPHATE

Frequent: hemolytic anemia in G-6-PD deficiency
Occasional: neutropenia; GI disturbance; methemoglobinemia
Rare: CNS symptoms; hypertension; arrhythmias

PROGUANIL (*PALUDRINE; MALARONE* [WITH ATOVAQUONE])

Occasional: oral ulceration; hair loss; scaling of palms and soles; urticaria
Rare: hematuria (with large doses); vomiting; abdominal pain; diarrhea (with large doses); thrombocytopenia

PYRANTEL PAMOATE (*ANTIMINTH*, AND OTHERS)

Occasional: GI disturbance; headache; dizziness; rash; fever

PYRETHRINS WITH PIPERONYL BUTOXIDE (*A-200*, AND OTHERS)

Occasional: allergic reactions

PYRIMETHAMINE *(DARAPRIM)*

Occasional: blood dyscrasias; folic acid deficiency
Rare: rash; vomiting; convulsions; shock; possibly pulmonary eosinophilia; fatal cutaneous reactions with pyrimethamine-sulfadoxine *(Fansidar)*

QUINACRINE

Frequent: disulfiram-like reaction with alcohol; nausea and vomiting; colors skin and urine yellow
Occasional: headache; dizziness
Rare: rash; fever; psychosis; extensive exfoliative dermatitis in patients with psoriasis

QUININE DIHYDROCHLORIDE AND QUININE SULFATE

Frequent: cinchonism (tinnitus, headache, nausea, abdominal pain, visual disturbance)
Occasional: deafness; hemolytic anemia; other blood dyscrasias; photosensitivity reactions; hypoglycemia; arrhythmias; hypotension; fever
Rare: blindness; sudden death if injected too rapidly; hypersensitivity reaction with TTP-HUS

SODIUM STIBOGLUCONATE *(PENTOSTAM)*

Frequent: myalgia and arthralgia (typically, large joint, may or may not be symmetric); malaise, fatigue and weakness; headache; anorexia; nausea; increased aminotransferases; increased amylase and lipase; T-wave flattening or inversion
Occasional: abdominal pain; liver damage; bradycardia; leukopenia; thrombocytopenia; rash; vomiting
Rare: diarrhea; pruritus; myocardial damage; hemolytic anemia; renal damage; shock; sudden death

SPIRAMYCIN *(ROVAMYCINE)*

Occasional: GI disturbance
Rare: allergic reactions

SULFONAMIDES

Frequent: allergic reactions (rash, photosensitivity, drug fever)
Occasional: kernicterus in newborn; renal damage; liver damage; Stevens-Johnson syndrome (particularly with long-acting sulfonamides); hemolytic anemia; other blood dyscrasias; vasculitis
Rare: transient acute myopia; pseudomembranous colitis; reversible infertility in men with sulfasalazine; CNS toxicity with trimethoprim-sulfamethoxazole in patients with AIDS

SURAMIN SODIUM

Frequent: vomiting; pruritus; urticaria; paresthesias; hyperesthesia of hands and feet; peripheral neuropathy; photophobia
Occasional: kidney damage; blood dyscrasias; shock; optic atrophy

TETRACYCLINES

(doxycycline—*Vibramycin*, and others; tetracycline hydrochloride—*Sumycin*, and others)
Frequent: GI disturbance; bone lesions and staining and deformity of teeth in children up to 8 years old, and in the newborn when given to pregnant women after the fourth month of pregnancy
Occasional: malabsorption; enterocolitis; photosensitivity reactions; increased azotemia with renal insufficiency (except doxycycline, but exacerbation of renal failure with doxycycline has been reported); hepatic injury; parenteral doses may cause serious liver damage, especially in pregnant women and patients with renal disease receiving 1 gram or more daily; esophageal ulcerations; cutaneous and mucosal hyperpigmentation
Rare: allergic reactions, including serum sickness and anaphylaxis; pseudomembranous colitis; blood dyscrasias; drug-induced lupus; autoimmune hepatitis; increased intracranial pressure; fixed-drug eruptions; transient acute myopia; blurred vision; diplopia; papilledema; photoonycholysis and onycholysis; aggravation of myasthenic symptoms with IV injection, reversed with calcium; possibly transient neuropathy; hemolytic anemia

TINIDAZOLE *(TINDAMAX)*

Occasional: metallic taste; GI symptoms; rash
Rare: weakness

TRIMETHOPRIM (*PROLOPRIM*, AND OTHERS)

Frequent: nausea and vomiting with high doses
Occasional: megaloblastic anemia; thrombocytopenia; neutropenia; rash; fixed drug eruption
Rare: pancytopenia; hyperkalemia

TRIMETHOPRIM/SULFAMETHOXAZOLE (*BACTRIM*, *SEPTRA*, AND OTHERS)

Frequent: rash; fever; nausea and vomiting
Occasional: hemolysis in G-6-PD deficiency; acute megaloblastic anemia; granulocytopenia; thrombocytopenia; pseudomembranous colitis; kernicterus in newborn; hyperkalemia
Rare: agranulocytosis; aplastic anemia; hepatotoxicity; Stevens-Johnson syndrome; aseptic meningitis; fever; confusion; depression; hallucinations; deterioration in renal disease; intrahepatic cholestasis; methemoglobinemia; pancreatitis; ataxia; CNS toxicity in patients with AIDS; renal tubular acidosis; hyperkalemia

SAFETY OF ANTIPARASITIC DRUGS IN PREGNANCY

Drug	Toxicity in Pregnancy	Recommendations	FDA
Albendazole (*Albenza*)	Teratogenic and embryotoxic in animals	Caution*	C
Amphotericin B (*Fungizone*, and others)	None known	Caution*	B
Amphotericin B liposomal *(AmBisome)*	None known	Caution*	B
Artemether/lumefantrine *(Coartem, Riamet)*[1]	Embryo-fetal loss in rats and and rabbits	Contraindicated during 1st trimester; caution 2nd and 3rd trimesters*	C
Artesunate[2]	Embryocidal and teratogenic in rats	Contraindicated during 1st trimester; caution 2nd and 3rd trimesters*	N/A
Atovaquone *(Mepron)*	Maternal and fetal toxicity in animals	Caution*	C
Atovaquone/proguanil *(Malarone)*[3]	Maternal and fetal toxicity in animals	Caution*	C

Drug	Toxicity in Pregnancy	Recommendations	FDA
Azithromycin (*Zithromax*, and others)	None known	Probably safe	B
Benznidazole *(Rochagan)*	Unknown	Contraindicated	N/A
Benzyl alcohol lotion *(Ulesfia Lotion)*	Unknown	Probably safe	B
Chloroquine (*Aralen*, and others)	None known with doses recommended for malaria prophylaxis	Probably safe in low doses	C
Clarithromycin (*Biaxin*, and others)	Teratogenic in animals	Contraindicated	C
Clindamycin (*Cleocin*, and others)[4]	None known	Caution*	B
Crotamiton *(Eurax)*	Unknown	Caution*	C
Dapsone	None known; carcinogenic in rats and mice; hemolytic reactions in neonates	Caution*, especially at term	C
Diethylcarbamazine (DEC; *Hetrazan*)	Not known; abortifacient in one study in rabbits	Contraindicated	N/A
Diloxanide *(Furamide)*	Safety not established	Caution*	N/A
Doxycycline (*Vibramycin*, and others)	Tooth discoloration and dysplasia inhibition of bone growth in fetus; hepatic toxicity and azotemia with IV use in pregnant patients with decreased renal function or with overdosage	Contraindicated	D
Eflornithine *(Ornidyl)*	Embryocidal in animals	Contraindicated	C
Fluconazole (*Diflucan*, and others)	Teratogenic	Contraindicated for high dose; caution* for single dose	C
Flucytosine *(Ancoban)*	Teratogenic in rats	Contraindicated	C
Furazolidone *(Furoxone)*	None known; carcinogenic in rodents; hemolysis with G-6-PD deficiency in newborn	Caution*; contraindicated at term	N/A
Hydroxychloroquine *(Plaquenil)*	None known with doses recommended for malaria prophylaxis	Probably safe in low doses	C
Itraconazole (*Sporanox*, and others)	Teratogenic and embryotoxic in rats	Caution*	C
Iodoquinol (*Yodoxin*, and others)	Unknown	Caution*	C
Ivermectin *(Stromectol)*[5]	Teratogenic in animals	Contraindicated	C
Ketoconazole (*Nizoral*, and others)	Teratogenic and embryotoxic in rats	Contraindicated; topical probably safe	C
Lindane	Absorbed from the skin; potential CNS toxicity in fetus	Contraindicated	C
Malathion, topical *(Ovide)*	None known	Probably safe	B
Mebendazole *(Vermox)*	Teratogenic and embryotoxic in rats	Caution*	C
Mefloquine *(Lariam)*[6]	Teratogenic in animals	Caution*	C
Meglumine *(Glucantine)*	Not known	Caution*	N/A
Metronidazole (*Flagyl*, and others)	None known—carcinogenic in rats and mice	Caution*	B
Miconazole *(Monistat i.v.)*	None known	Caution*	C
Miltefosine *(Impavido)*	Teratogenic in rats and induces abortions inanimals	Contraindicated; effective contraception must be used for 2 months after the last dose	N/A
Niclosamide *(Niclocide)*	Not absorbed; no known toxicity in fetus	Probably safe	B
Nitazoxanide *(Alinia)*	None known	Probably safe	B
Oxamniquine *(Vansil)*	Embryocidal in animals	Contraindicated	N/A
Paromomycin	Poorly absorbed; toxicity in fetus unknown	Oral capsules probably safe	C

Drug	Toxicity in Pregnancy	Recommendations	FDA
Pentamidine (*Pentam 300, NebuPent*, and others)	Safety not established	Caution*	C
Permethrin (*Nix*, and others)	Poorly absorbed; no known toxicity in fetus	Probably safe	B
Praziquantel *(Biltricide)*	None known	Caution	B
Primaquine	Hemolysis in G-6-PD deficiency	Contraindicated	C
Pyrantel pamoate (*Antiminth*, and others)	Absorbed in small amounts; no known toxicity in fetus	Probably safe	C
Pyrethrins and piperonyl butoxide (*A-200*, and others)	Poorly absorbed; no known toxicity in fetus	Probably safe	C
Pyrimethamine *(Daraprim)*[7]	Teratogenic in animals	Caution*; contraindicated during 1st trimester	C
Quinacrine *(Atabrine)*	Safety not established	Caution*	N/A
Quinidine	Large doses can cause abortion	Probably safe	C
Quinine *(Qualaquin)*	Large doses can cause abortion; auditory nerve hypoplasia, deafness in fetus; visual changes, limb anomalies, visceral defects also reported	Caution*	C
Sodium stibogluconate *(Pentostam)*	Not known	Caution*	N/A
Spiramycin *(Rovamycine)*[7]	None known	Probably safe	N/A
Sulfonamides	Teratogenic in some animal studies; hemolysis in newborn with G-6-PD deficiency; increased risk of kernicterus in newborn	Caution*; contraindicated at term	C
Suramin sodium *(Germanin)*	Teratogenic in mice	Caution*	N/A
Tetracycline (*Sumycin*, and others)	Tooth discoloration and dysplasia, inhibition of bone growth in fetus; hepatic toxicity and azotemia with IV use in pregnant patients with decreased renal function or with overdosage	Contraindicated	D
Tinidazole *(Tindamax)*	Increased fetal mortality in rats	Caution*	C
Trimethoprim	Folate antagonism; teratogenic in rats	Caution*	C
Trimethoprim-sulfamethoxazole (*Bactrim*, and others)	Same as sulfonamides and trimethoprim	Caution*; contraindicated at term	C

MANUFACTURERS OF DRUGS USED TO TREAT PARASITIC INFECTIONS

A-200 (Hogil)—pyrethrins and piperonyl butoxide
albendazole—*Albenza* (GlaxoSmithKline)
Albenza (GlaxoSmithKline)—albendazole
Alinia (Romark)—nitazoxanide
AmBisome (Gilead)—amphotericin B, liposomal
amphotericin B—*Fungizone* (Apothecon), others
amphotericin B, liposomal—*AmBisome* (Gilead)
Ancobon (Valeant)—flucytosine
§ *Antiminth* (Pfizer)—pyrantel pamoate
• *Aralen* (sanofi-aventis)—chloroquine HCl and chloroquine phosphate
§ artemether—*Artenam* (Arenco, Belgium)
artemether/lumefantrine—*Coartem, Riamet* (Novartis)
§ *Artenam* (Arenco, Belgium)—artemether
• † artesunate—(Guilin No. 1 Factory, People's Republic of China)
atovaquone—*Mepron* (GlaxoSmithKline)
atovaquone/proguanil—*Malarone* (GlaxoSmithKline)
azithromycin—*Zithromax* (Pfizer), others
• *Bactrim* (AR Scientific)—TMP/Sulfa
Benzyl alcohol lotion—*Ulesfia* (Sciele)
§ benznidazole—*Rochagan* (Brazil)
• *Biaxin* (Abbott)—clarithromycin
Biltricide (Bayer)—praziquantel
† bithionol—*Bitin* (Tanabe, Japan)
† *Bitin* (Tanabe, Japan)—bithionol
§ *Brolene* (Aventis, Canada)—propamidine isethionate
chloroquine HCl and chloroquine phosphate—Aralen (sanofi-aventis), others
• clarithromycin—*Biaxin* (Abbott), others
• *Cleocin* (Pfizer)—clindamycin
clindamycin—*Cleocin* (Pfizer), others
Coartem (Novartis)—artemether/lumefantrine
crotamiton—*Eurax* (Ranbaxy)
dapsone—(Jacobus)
§ *Daraprim* (GlaxoSmithKline)—pyrimethamine USP
† diethylcarbamazine citrate (DEC)—*Hetrazan*
• *Diflucan* (Pfizer)—fluconazole
§ diloxanide furoate—*Furamide*
doxycycline—*Vibramycin* (Pfizer), others
§ eflornithine (Difluoromethylornithine, DFMO)—*Ornidyl* (Aventis)
§ *Egaten* (Novartis)—triclabendazole
Elimite (Allergan)—permethrin
Eurax (Ranbaxy)—crotamiton
• *Flagyl* (Pfizer)—metronidazole
§ *Flisint* (Sanofi-Aventis, France)—fumagillin
fluconazole—*Diflucan* (Pfizer), others
flucytosine—*Ancobon* (Valeant)
§ fumagillin—*Flisint* (Sanofi-Aventis, France)
• *Fungizone* (Apothecon)—amphotericin
§ *Furamide*—diloxanide furoate
§ furazolidone—*Furoxone* (Roberts)
§ *Furoxone* (Roberts)—furazolidone
† *Germanin* (Bayer, Germany)—suramin sodium
§ *Glucantime* (Aventis, France)—meglumine antimonate
† *Hetrazan*—diethylcarbamazine citrate (DEC)
§ *Impavido* (Paladin, Montreal, Canada)—miltefosine
iodoquinol—*Yodoxin* (Glenwood), others
itraconazole—*Sporanox* (Ortho-McNeil-Janssen), others
ivermectin—*Stromectol* (Merck)
ketoconazole—*Nizoral* (Janssen), others
† *Lampit* (Bayer, Germany)—nifurtimox
§ *Leshcutan* (Teva, Israel)—topical paromomycin
lumefantrine/artemether—*Coartem, Riamet* (Novartis)
Malarone (GlaxoSmithKline)—atovaquone/proguanil
malathion—*Ovide* (Taro)
mebendazole
mefloquine
§ meglumine antimonate—*Glucantime* (Aventis, France)

CHAPTER 241

Immunomodulating Agents

Timothy R. La Pine • Harry R. Hill

Considerable clinical interest and basic science research into the functional mechanisms of the immune response and identification of the specific biologic factors that modulate this response have been generated lately. There are over tens of thousands of citations in the peer-reviewed medical literature on this topic. This research has established that a critical and delicate balance in the regulation of both cellular and humoral function is essential for complete immunologic response to invasive pathogens and that alteration of this regulation may have potential clinical significance. Attempts to augment immune function in the challenged host or during specific immunodeficiency states have focused on numerous modifiers of immune biologic response. These efforts, in combination with advances made in hybridoma, recombinant DNA technology, and proteomics, have resulted in numerous clinical trials conducted to explore the therapeutic utility of immunomodulating agents in the treatment of specific human disease states.[54] Biologic agents used to manipulate immune regulation for the prevention and management of infectious diseases in infants and children are discussed.

MONOCLONAL ANTIBODIES

The use of serum antibody therapy, in the late 1800s, was among the first clinical attempts to modulate the immune response in the treatment of human sepsis. By the middle 1930s, serum-based therapy was the standard of care for many infectious illnesses, particularly pneumonia. Controlled trials during that time demonstrated that the administration of type-specific pneumococcal serum reduced the mortality rate by 50 percent in patients with pneumococcal pneumonia.[49,50,84] With the introduction of antimicrobial pharmacologic agents in the 1940s, the use of serum antibody therapy for sepsis became less popular. The development of hybridoma technology by Kohler and Milstein[153] in 1975, however, provided the means to generate virtually unlimited amounts of monoclonal antibodies for potential clinical use. This technology in combination with the advances in recombinant DNA technology has allowed researchers to generate highly specific human monoclonal antibodies and to humanize murine monoclonal antibodies.[33,293] Monoclonal antibodies now are considered attractive molecules to be used potentially as antimicrobial and antiviral agents and immunomodulators, to deliver pharmacologic substances to sites of inflammation, or even to target certain cancerous tissues. This advance has led to the development of monoclonal antibody–based therapies to treat sepsis, septic shock, hemolytic-uremic syndrome, viral diseases, and a number of inflammatory diseases in infants, children, and adults.

A monoclonal antibody could, in theory, be generated that would alter the clinical course of any infectious or inflammatory disease state. This hypothesis has fostered numerous studies evaluating the use of monoclonal antibodies in a variety of clinical diseases, particularly those related to alloimmune and autoimmune phenomena.[62,75,113,185,231] The use of monoclonal antibodies to alter the pathogenesis of sepsis and septic shock also has received considerable experimental and clinical attention. These efforts have focused on two phases in the development of the septic shock syndrome: (1) to block bacteria and their components that induce shock and (2) to modify the release and action of the proinflammatory mediators that lead to septic shock.

Monoclonal antibody preparations to block bacteria or their components in the development of septic shock were initially employed in early studies using type-specific antisera against *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*.[50] Attempts using monoclonal antibody therapy to alter the pathogenesis of bacterial sepsis leading to septic shock have focused on group B streptococcus (GBS) and *Escherichia coli*. These two bacteria are significant causes of neonatal morbidity and mortality. Infants usually acquire these bacterial infections from exposure in the birth canal; however, only a small number of the exposed infants actually develop bacterial sepsis. Factors predisposing infants to acquisition of infection with these organisms include prematurity, prolonged rupture of membranes, and maternal sepsis. Neonatal infections occur more commonly with bacteria that possess specific capsular polysaccharides (i.e., the type III polysaccharide of GBS or the K-1 capsule of *E. coli*). Bacteria bearing these capsules are able to avoid opsonization and subsequent phagocytic killing by polymorphonuclear leukocytes (PMNs). Neonates with deficiencies of type-specific antibodies to these bacterial capsular antigens due to prematurity, which contributes to decreased maternal transplacental antibody transport, or inadequate maternal stores are predisposed to acquisition of GBS and *E. coli* infections.[125] These observations led investigators to hypothesize that passive antibody administration may be beneficial in preventing or reducing neonatal morbidity and mortality observed with these bacterial infections.

Rebecca Lancefield in 1933 originally demonstrated a protective efficacy for GBS antibody therapy using rabbit

antisera. She established that this protective efficacy is type specific and classified three types of GBS strains. Antisera raised against type II or type III GBS did not protect against infection with type I bacteria. These experiments also suggested that antibodies to group B non–type-specific determinants (i.e., expressed on all GBS bacteria) are not protective.[93,169-171] Further experiments by Lancefield and coworkers with type I GBS demonstrated that antibodies to both carbohydrate and protein capsular components can be protective.[169,171] The first human studies to suggest that the administration of antibody to the infecting strain of bacteria could improve survival rates from early-onset GBS in infants occurred in the middle 1970s.[255-258] In these studies, fresh whole blood either containing or lacking opsonic antibody was administered to infants with early-onset GBS disease. All nine infants who demonstrated a rise in opsonic antibody after transfusion survived. In contrast, three of the six infants (50%) who received blood lacking antibody to their infection strain died.[254] Subsequent studies have suggested that intravenous immune globulins (IVIG) could offer some protection against GBS infections in experimental animal models.[87,130] Because of their lack of specificity and decreased opsonic activity, however, polyclonal-type IVIG antibody preparations have had only variable and limited ability to alter the course and outcome of GBS or other bacterial infections in clinical trials.[121]

The development of monoclonal antibodies to GBS type III occurred in the early 1980s.[255-258] The GBS type III–specific antibodies, which were of the immunoglobulin (Ig) M class, protected rats against intraperitoneal infection with homologous type GBS. Survival rates were 95 to 100 percent for rats protected by monoclonal antibody compared with 17 percent for unprotected rats. Protection was afforded even when therapy was delayed up to 24 hours after inoculation. Antibody administration resulted in the rapid accumulation of PMNs at the site of infection and prevented the depletion of bone marrow granulocyte stores commonly seen in animal models and human neonates with GBS infection.[256] Monoclonal IgG and IgA antibody preparations also have been generated to type III GBS.[23,212,255] A protective effect in animal models of GBS infection for all three immunoglobulin isotypes has been established.[257] In GBS infections, the ability of an antibody isotype preparation to activate the complement system is related directly to its protective and opsonic activity.[258] IgM is much more active in triggering complement than are monoclonal IgG and IgA preparations,[173,258] which may explain why monoclonal IgM is quantitatively more effective against GBS infections.[124,127,258] Although human monoclonal IgM antibodies to GBS are available and have demonstrated effectiveness in reducing mortality in animal models of GBS sepsis, they have yet to be tried clinically to prevent or to attenuate GBS sepsis and septic shock in human neonates.[234,258]

Concomitant with the studies of monoclonal antibody preparations for use in experimental models of GBS infections were similar studies using monoclonal preparations in *E. coli* sepsis. *E. coli* is an antigenically complex, gram-negative bacterium having more than 150 somatic (O) and 100 capsular (K) antigens. Several factors associated with *E. coli* have been implicated as contributing to the virulence of these organisms. Among these, the K-1 capsular polysaccharide and lipopolysaccharide (LPS) have received the most attention.[28] The K-1 capsular polysaccharide on *E. coli* as a contributing factor to the virulence of this organism was suggested first by Robbins and colleagues in 1974.[239] Subsequent studies established that *E. coli* strains that possess the K-1 capsular polysaccharide are resistant to opsonization through the alternative complement pathway.[30,263] Several investigators have shown that antibody preparations to the K-1 capsular polysaccharide are opsonic and protective against lethal *E. coli* bacteremia in animals.[29] Although protection has been demonstrated primarily with IgM antibody, polyclonal hyperimmune IgG has shown some protection in animal models of lethal *E. coli* sepsis.[233] Because the serum from neonates is deficient in opsonic activity for *E. coli*, some investigators suggested that the administration of antibody against *E. coli* K-1 would enhance neonatal resistance to infections with this organism.[31,60] Investigators since have developed murine and human monoclonal IgM antibodies to *E. coli* K-1 and demonstrated that these antibodies are opsonic and protective against lethal *E. coli* infections in animal models.[233] Staphylococci are a major cause of acquired infections in prematurely born infants. Antibiotic resistance among staphylococcal species in these immunocompromised patients is of significant concern. A human chimeric monoclonal antibody has been generated that is opsonic for *Staphylococcus epidermidis* and *Staphylococcus aureus.* In animal models of *S. epidermidis* and *S. aureus* sepsis, this monoclonal antibody enhanced bacterial clearance and significantly improved survival against both staphylococcal species. Clinical trials with this monoclonal antibody have been performed to determine the clinical usefulness of monoclonal antibody preparations in preventing nosocomial staphylococcal infections in high-risk preterm neonates.[88,282]

During the past several decades, the importance of pneumococcal vaccination for individuals at risk for acquiring infection has been underscored by the emergence of antibiotic resistance among pneumococcal strains and the increased prevalence of invasive pneumococcal disease in immunocompromised patients. Unfortunately, pure pneumococcal capsular polysaccharide vaccines are poorly immunogenic in many immunodeficient patients who are at risk for acquiring infection. This concern has led to the development of monoclonal antibodies against type-specific pneumococcal infections. A human monoclonal IgM antibody has been generated and shown to provide type-specific protection against lethal pneumococcal infections in mice, even in the presence of complement deficiency.[297] Thus, type-specific monoclonal antibody preparations likely could provide protection against pneumococcal infection in high-risk immunocompromised humans.

The use of monoclonal antibodies as a single-agent therapy to treat or to prevent bacterial sepsis has been limited to experimental animal models, primarily because of the narrow spectrum of monoclonal antibody therapy and the exceedingly large number of patients required to demonstrate the efficacy of human monoclonal antibody

therapy in clinical trials. The future clinical use of monoclonal antibodies directed at bacteria or their components in the treatment of sepsis requires several clinical considerations. First, because antibodies are more effective in preventing an infection than in treating an established infection, monoclonal antibody therapy is most useful when it is administered early in the course of a disease. Second, the successful implementation of monoclonal antibody therapy directed at a specific pathogen requires refinements in diagnostic laboratory methodology to hasten identification of pathogens, leading to early treatment. Third, monoclonal antibody therapy is pathogen specific, which is problematic in dealing with unknown infections early in their course and with mixed infections with multiple organisms or serotypes. For pathogens that are antigenically variable, use of monoclonal antibody cocktail preparations that combine monoclonal antibodies to common antigenic serotypes may be beneficial. Antibody cocktails also may be designed to include monoclonal antibodies of different isotypes (IgM, IgG, IgA) to further enhance their effectiveness. Fourth, combination therapy with monoclonal antibodies and antimicrobial chemotherapy agents may be an alternative means to treat bacteria and their components in the development of septic shock. Such therapies could potentially reduce the amount or duration of antibiotic treatment needed and reduce the number of antibiotic-resistant pathogens. Combination therapy also may be clinically beneficial in cases in which the antimicrobial agents are toxic themselves. Fifth, monoclonal antibodies may elicit self-neutralizing antibodies. Thus, the administration of a monoclonal antibody could promote the production of antibody against the monoclonal antibody itself, which would diminish the clinical response and potentially cause severe anaphylaxis in cases of antibody retreatment. Likewise, widespread use of monoclonal antibody therapy could select for antibody-resistant pathogens or other serotypes or even entirely different infecting organisms.[167]

Monoclonal antibodies directed against viral glycoprotein complexes or that immune modulate through other mechanisms are also being developed and evaluated for human use for a variety of viral diseases. Palivizumab, a humanized F protein monoclonal antibody, is routinely administered to preterm infants and other high-risk infants for immunoprophylaxis against respiratory syncytial virus (RSV) infection and disease.[95] It also is used for prophylaxis against RSV infection in older high-risk subjects, such as transplant recipients and children with cystic fibrosis.[239,240] In addition, palivizumab is administered in some patients to treat established RSV infections in immune compromised patients, while awaiting immune reconstitution. Recently, a recombinant human antirabies monoclonal antibody has been tested in India. It appears to be safe and equally efficacious than conventional serum-derived rabies immune globulin (RIG) and may soon replace the use of RIG for postexposure prophylaxis.[103,214,215] Monoclonal antibodies directed against vaccinia virus have been developed and tested in preclinical animal models as potential therapeutic antibodies for treatment of smallpox,[59] especially in viral glycoprotein complexes. The anti-angiogenic monoclonal antibody bevacizumab (Avastin) is also been used to treat recurrent respiratory papillomatosis.[19] Monoclonal antibodies directed against glycoprotein N of human cytomegalovirus (CMV) enhances neutralizing antibody activity in vitro and possibly in the future may be used to enhance natural humoral immunity response against human CMV.[157] In addition, postexposure immunoprophylaxis and treatment of alphavirus infections, such as Chikungunya virus, using human monoclonal antibodies are also being studied.[94]

Researchers have examined the possible blockade of the proinflammatory cascade that accompanies severe infections.[1,14,99,166] The experimental attempts using monoclonal antibodies to modify the release and action of the proinflammatory mediators that lead to septic shock have focused on the proinflammatory effects of the cytokine family, endotoxin, and the functions of neutrophils and complement. Eculizumab, a humanized monoclonal anti-C5 complement antibody that prevents the activation of terminal complement pathway, is now used as treatment in atypical hemolytic uremic syndrome.[271]

Treatment with monoclonal antibodies, such as rituximab, an antiCD20 therapeutic monoclonal antibody, and infliximab, an anti–tumor necrosis factor–α (TNF-α) monoclonal antibody, in patients with immune disorders increases the risk for certain infections, such as nontuberculous mycobacteria.[36,236]

THE CYTOKINES

Lymphokines and Monokines

The cytokines are a family of small soluble protein molecules responsible for cell-to-cell communication. They are produced by several cell types and play crucial roles in many biologic processes, including growth, inflammation, immunity, and hematopoiesis. During infection, genes for nearly all the cytokines are expressed. The biologic activity of the prototype cytokines, the lymphokines and monokines, include interleukins (ILs) and TNF-α; these molecules, along with the granulocyte colony-stimulating factors, have received considerable attention as potential immunomodulatory agents. In response to pathogen invasion, these cytokines perform a complex series of interactions to initiate a cascade of biologic events resulting in the propagation and subsequent regulation of the inflammatory response, leading to pathogen alienation while maintaining host preservation. Thus, the cytokine family, through a complex web of interactions, functions to initiate and then both to upregulate and downregulate the inflammatory response. On the basis of their roles of either upregulating or downregulating immune responsiveness, the cytokines generally and historically have been classified as either proinflammatory or anti-inflammatory molecules. Although many cytokines have the potential to perform dual functions, either directly or indirectly, their proinflammatory or anti-inflammatory properties are of considerable basic science and clinical therapeutic interest.*

*References 27, 51, 70, 91, 166, 174, 184, 226.

Some prominent proinflammatory cytokines and their cellular sources are listed in Table 241-1. TNF-α and IL-1 generally are considered to be prominent early proinflammatory mediators. They induce gene expression of other proinflammatory cytokines, including IL-6 and IL-8, leading to neutrophil activation, recruitment, and degranulation. TNF-α and IL-1 also activate a secondary cascade of inflammatory mediators, including arachidonic acid–derived prostaglandin I_2, thromboxane A_2, prostaglandin E_2, platelet-activating factor, and the complement system. The colony-stimulating factors and IL-3 also are proinflammatory cytokines that induce bone marrow stem cell production of granulocytes and monocytes in addition to activating neutrophils and inducing production of IL-1 and TNF-α.*

Prominent among the anti-inflammatory cytokines (Table 241-2) are IL-4, IL-10, IL-13, and transforming growth factor–β. These cytokines may block endotoxin induction of IL-1 and TNF-α and suppress lymphocyte and monocyte function. In addition, IL-1 receptor antagonist blocks the proinflammatory action of IL-1 by binding its receptor.†

Considerable experimental and clinical interest has focused on the proinflammatory cytokines TNF-α and IL-1 as important early mediators in the pathogenesis of sepsis and septic shock syndrome. The basis for the potential therapeutic utility of these two cytokines in human disease states involves two clinically distinct hypotheses: (1) excessive cytokine production results in host immune injury, leading to severe shock; and (2) deficient cytokine production renders a host susceptible to infection by invasive pathogens.[166]

The hypothesis that cytokine overproduction can lead to severe lethal shock is demonstrated in several animal models and is suggested in patients with overwhelming sepsis. The outer membranes of gram-negative bacteria contain lipopolysaccharides or endotoxin, which induce the early proinflammatory cytokines TNF-α and IL-1. Although these cytokines may protect the host from infection, if they are expressed in excessive amounts, their effects can result in multiple organ failure and death. During severe sepsis, the levels of both TNF-α and IL-1 increase proportionately with the degree of hypotension and organ failure. The combination of these two cytokines can result in synergism over their individual effects by severalfold, leading to lethal septic shock syndrome.[39,40] In animal models of shock and gram-negative sepsis, TNF-α levels rise rapidly after injection of bacteria or endotoxin, reaching peak concentrations at 60 to 90 minutes, whereas IL-1 levels rise more slowly, peaking at 180 minutes. A similar time course response has been observed in human subjects injected with endotoxin.[40,206] Children with septicemia and purpura fulminans and children with meningococcal disease demonstrated an association between morbidity and mortality and high serum levels of TNF-α and IL-1.[100,214] These studies and others implicate TNF-α and IL-1 as prominent modulators in the development of the septic shock syndrome and suggest that a potential therapeutic benefit may be obtained by inhibiting the production of these cytokines and reducing their proinflammatory effects.

Experimental attempts to attenuate the excessive proinflammatory cytokine activity of TNF-α and IL-1 have focused on (1) inhibiting release of endotoxin, (2) blocking endotoxin–target cell binding and preventing the transmembrane signaling mechanisms leading to production of TNF-α and IL-1, (3) controlling the synthesis of TNF-α and IL-1 by inhibiting or suppressing specific cytokine gene transcription and translation, (4) inhibiting release of TNF-α and IL-1, (5) administering TNF-α and IL-1 neutralizing antibodies and soluble receptors, (6) producing and administering TNF-α and IL-1 receptor antagonists that block specific cytokine binding to target cell receptors, and (7) blocking TNF-α or IL-1 intracellular transmembrane signaling mechanisms and preventing their action on target cells.[174]

The use of monoclonal anti-endotoxin antibodies to inhibit the binding of endotoxin to its target cells has received considerable attention. Numerous in vitro and in vivo animal experiments have suggested that blocking of endotoxin leads to improved survival by inhibiting proinflammatory cytokine production and expression.[216] The initial clinical studies in patients with gram-negative bacteremia treated with immunoglobulin preparations directed against endotoxin demonstrated a significant reduction in mortality rates.[15,248] Further studies suggested a reduction of septic shock in similarly treated high-risk surgical patients.[15] These observations led to the development of several clinical trials using human monoclonal anti-endotoxin antibodies. HA-1A is a human monoclonal antibody against the lipid A moiety of bacterial endotoxin. The mechanism of HA-1A action is to block endotoxin triggering of the intracellular events leading to proinflammatory cytokine synthesis. In placebo-controlled clinical trials of HA-1A, either HA-1A or placebo was infused during the course of 20 minutes to patients with severe sepsis. These patients also received cardiopulmonary support and antibacterial therapy. The etiologic agents of sepsis included *E. coli*, *Pseudomonas*, and *Klebsiella* and *Enterobacter* spp. The authors reported that HA-1A significantly reduced the incidence of mortality in adults with septic shock and gram-negative bacteremia. The mortality rate for those patients who were in severe shock before receiving HA-1A was reduced by 42 percent.[298] Although these early clinical studies using HA-1A were encouraging, a protective role for anti-endotoxin antibodies has not been established in subsequent clinical trials.[189] Anti-endotoxin therapy may be more effective if it is given earlier during the sepsis syndrome before the development of shock. Because bacterial lysis caused by antibiotics is an ongoing process and results in further release of endotoxin, multiple dosing of anti-endotoxin antibodies also may prove beneficial in treating sepsis. The future clinical use of anti-endotoxin antibodies may be in combination with other immunomodulation therapies, directed at simultaneously blocking several steps in both the propagation and action of proinflammatory cytokines.

Studies of cytokine inhibition have focused on controlling TNF-α and IL-1 with anti–TNF-α antibodies

TABLE 241-1 **Proinflammatory Cytokines**

Cytokine	Function	Predominant Cell Source
Tumor necrosis factor–α	Stimulates interleukin-6 and colony-stimulating factors Depresses erythropoiesis, stimulates interleukin-8 and interleukin-9 Promotes tumor necrosis and endotoxic shock	Monocytes and macrophages
Interleukin-1	Stimulates proliferation and differentiation of T and B lymphocytes Stimulates T lymphocytes to produce interleukin-2 Promotes colony-stimulating factor, interleukin-8 and interleukin-9 production, and endotoxic shock	Macrophages, astrocytes, monocytes, fibroblasts, keratinocytes, B cells, corneal epithelium, and other cell types
Interleukin-2	Stimulates growth of T lymphocytes Stimulates B-lymphocyte and monocyte differentiation Increases cytotoxicity of T lymphocytes and natural killer cells	Activated T lymphocytes
Interleukin-3	Multipotential hematopoietic cell growth factor Stimulates early B and T lymphocytes Mast cell growth factor	Activated T lymphocytes, natural killer cells
Interleukin-5	Stimulates eosinophil formation and differentiation Augments T lymphocyte cytotoxicity and proliferation of B lymphocytes	T lymphocytes, mast cells
Interleukin-7	Supports growth of pre-B lymphocytes Stimulates T lymphocytes	B lymphocytes, bone marrow fibroblasts, monocytes
Interleukin-8	Stimulates neutrophil, monocyte, and lymphocyte activation chemotaxis	Monocytes
Interleukin-9	Stimulates neutrophil, monocyte, and lymphocyte activation chemotaxis Stimulates erythroid progenitors, helper T-lymphocyte growth factor	T lymphocytes
Interleukin-11	T lymphocyte–dependent stimulator of B lymphocytes	Bone marrow fibroblasts
Interleukin-12	Stimulates helper T-lymphocyte differentiation and interleukin-2 production Stimulates interferon-γ production Increases cytotoxicity of natural killer cells	T and B lymphocytes, lymphoblastoid cells
Interleukin-14	Stimulates proliferation of activated B lymphocytes Inhibits immunoglobulin secretion from B lymphocytes	T lymphocytes
Interleukin-15	Stimulates T-lymphocyte function and proliferation Enhances natural killer cell function	Monocytes and macrophages
Interleukin-16	Promotes migration of T lymphocytes	T lymphocytes
Interleukin-17	Stimulates interleukin-6 and interleukin-8 production	T lymphocytes
Interleukin-18	Stimulates interferon-γ and tumor necrosis factor–α production	Macrophages, mononuclear cells, and dendritic cells
Granulocyte colony-stimulating factor	Stimulates neutrophil colony formation	Monocytes and fibroblasts
Granulocyte-macrophage colony-stimulating factor	Stimulates granulocyte and monocyte formation Induces tumor necrosis factor	T lymphocytes, natural killer cells, endothelial cells, fibroblasts, and keratinocytes
Macrophage colony-stimulating factor	Activates monocytes and granulocytes Stimulates macrophage colony formation Induces interleukin-1 and tumor necrosis factor	Fibroblasts, monocytes, and endothelial cells

directed at these specific cytokines and their receptors. Control of proinflammatory cytokine synthesis is specific for each individual cytokine and requires an understanding of the unique temporal relationships these molecules have during the propagation of inflammatory responses. A critical aspect of TNF-α and IL-1 gene expression in a variety of cell types has been the reported exquisite sensitivity these cytokines have to bacterial endotoxin.[51,70,166,174] Human blood monocytes synthesize TNF-α and IL-1 in the presence of endotoxin. In the absence of endotoxin, however, gene expression occurs, but protein translation does not take place.[249] Thus, these cells may be viewed as being primed for bacterial endotoxin exposure. TNF-α and IL-1 transcription is suppressed by the anti-inflammatory cytokines IL-10, IL-13, and transforming growth factor–β, but the clinical therapeutic benefits these cytokines have in treating septic shock remain to be defined.[53,117,208,250] Agents blocking the

TABLE 241-2 **Anti-inflammatory Cytokines**

Cytokine	Function	Predominant Cell Source
Interleukin-4	Stimulates proliferation of T and B lymphocytes and megakaryocytes A growth factor for mast cells and erythroid precursors	T lymphocytes
Interleukin-6	Blocks endotoxin induction of interleukin-1 and tumor necrosis factor B and T lymphocyte–stimulating activity	Monocytes, T and B lymphocytes, fibroblasts, epithelial and endothelial cells
Interleukin-10	Blocks production of interleukin-1 and tumor necrosis factor Inhibits primary allogeneic T-lymphocyte responses Inhibits interleukin-2, interleukin-8, and granulocyte-macrophage colony-stimulating factor	T and B lymphocytes, macrophages and monocytes
Interleukin-13	Blocks production of interleukin-1, tumor necrosis factor, and interleukin-8 Suppresses nitric oxide formation	T lymphocytes
Interleukin-1 receptor antagonist	Binds interleukin-1 receptors, blocking interleukin-1 effects	Monocytes and macrophages
Transforming growth factor–β	Reduces endotoxin-induced interleukin-1 and tumor necrosis factor production	Monocytes and macrophages

lipoxygenase pathway of arachidonate metabolism also have been implicated in the reduction of TNF-α and IL-1 synthesis, and corticosteroids have been shown to suppress both TNF-α and IL-1 transcription and synthesis, but only when they have been administered before transcription has been initiated.[89,247] The use of corticosteroids in infants and children with bacterial meningitis has demonstrated that treatment with a combination of dexamethasone and antibiotics results in lower cerebrospinal fluid levels of TNF-α than occurs with treatment with placebo and antibiotics.[214] In addition, patients treated with corticosteroids had fewer neurologic symptoms.[147] Subsequent multicenter trials, however, have failed to establish a protective effect of corticosteroid use in the treatment of children with meningitis.[277] One possible explanation for this discrepancy may be that corticosteroids almost exclusively suppress endotoxin-induced, proinflammatory cytokine gene transcription but have little or no effect on proinflammatory cytokine translation.[70,259] Thus, some investigators have suggested that the early administration of corticosteroids, before transcription has been initiated, would block cytokine synthesis. Timing of corticosteroid administration, therefore, may account for some of the clinical variability seen with its use in children with meningitis. Clinical trials are focusing on TNF-α and IL-1 synthesis with the administration of corticosteroids either before or while antibiotics are administered. Similarly, the temporal use of antibiotics, corticosteroids, and anti-endotoxin therapy may result in an additive therapeutic benefit.

Neutralizing monoclonal antibodies against murine or human TNF-α have been shown to decrease mortality rates in several experimental animal models of sepsis.[20,197,270] Studies with soluble TNF-α receptors or their immunoadhesin constructs also have demonstrated an immunoprotective effect of TNF-α blockade in animal models of endotoxemia or bacteremia.[18] Although anti–TNF-α antibodies are being used with caution in humans, anti–TNF-α treatment in a limited number of patients with established septic shock resulted in increased vascular hemodynamics and left ventricular stroke volume.[111] The in vitro use of free soluble TNF-α receptors to bind TNF-α results in a 10- to 50-fold increase in binding affinity over that observed with anti–TNF-α monoclonal antibodies.[112] Results from phase II clinical trials using soluble TNF-α receptors, however, have not shown improvement in survival rates; moreover, administration of high doses actually increased the incidence of mortality.[112,245]

Certain naturally occurring substances inhibit IL-1 synthesis and action, but they also have effects on many of the other cytokines. Specific inhibitors of IL-1, however, have been identified. Most prominent of these is the IL-1 receptor inhibitor that competes with the binding of IL-1 to its cell surface receptor. Recombinant IL-1 receptor antagonist (IL-1ra) that blocks IL-1 effects has been studied in various animal models.[4,224] For instance, IL-1ra prevents death from endotoxic shock in rabbits.[224] The therapeutic use of IL-1ra in treating septic shock in early phase II human clinical trials showed improved survival rates at 28 days.[90] The subsequent randomized phase III trials, however, failed to show improvement in patients with severe shock.[89] Further clinical studies are ongoing. IL-1ra also has been used in treatment trials of patients with acute myelogenous leukemia. The uncontrolled production of IL-1 by leukemic blasts has been proposed to result in the continued proliferation of these cells and the development of acute myelogenous leukemia. Studies have shown that IL-1ra blocks the spontaneous proliferation and production of granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-1, and IL-6 in the peripheral blood and bone marrow cells of these patients.[235] The potential clinical use of IL-1ra is being investigated in patients with psoriasis, rheumatoid arthritis, and myelogenous leukemia.[114] Similarly, combination therapy with the simultaneous blockade of both TNF-α and IL-1 is being investigated in endotoxin models of shock and a number of clinical disease states.[243]

Another approach to attenuate excessive proinflammatory cytokine responses is the use of pharmacologic agents. Salyer and colleagues[246] demonstrated that

pentoxifylline, a methylxanthine derivative that blocks TNF-α transcription and production, could override some of the effects of TNF-α on PMNs. In their study, the profound decrease in human PMN chemotactic ability caused by excessive TNF-α was restored to normal by treatment with pentoxifylline. The specific mechanisms of pentoxifylline's effect are not known, but it has been shown to restore PMN membrane fluidity inhibited by TNF-α that is critical for cell movement.[220,221] Furthermore, pentoxifylline can block PMN adhesion to endothelium and result in decreased PMN respiratory burst activity, which is thought to be responsible for the improved survival rates seen in pentoxifylline-treated animal models of endotoxin-induced septic shock.[225] Some of the clinical trials using pentoxifylline in surgical patients with early evidence of systemic inflammation have suggested a cardioprotective effect, although other studies have been less convincing.[82,262] Pentoxifylline also has been evaluated in preterm infants with sepsis.[176] A total of 78 infants with documented sepsis were randomly assigned to receive pentoxifylline (5 mg/kg/hr for 6 hours on 6 successive days) or placebo. Pentoxifylline-treated infants had significantly lower levels of TNF-α but not of IL-1. Only 1 of 40 infants in the pentoxifylline-treated group died, compared with 6 of 38 in the control group (p <.05). Amrinone, a phosphodiesterase inhibitor, also has been shown to reduce TNF-α levels in LPS-challenged mice.[101] Thus, these and other pharmacologic agents may be useful in preventing or reducing some of the adverse and even fatal effects that are mediated by proinflammatory cytokines.

IVIG may have a potential inhibitory effect on proinflammatory cytokine activity. Patients in the active phase of Kawasaki disease have increased levels of TNF-α and IL-1. These cytokines have been postulated to stimulate local inflammatory responses by regulating leukocyte adherence and activation, leading to the vascular damage that is a critical clinical aspect of this disease. Another suggestion is that the effects of IVIG therapy in Kawasaki disease, and perhaps in other diseases, may be results of the attenuating production of the proinflammatory cytokines TNF-α and IL-1.[6,11,124] Animal models of LPS-induced TNF-α and IL-1 synthesis demonstrate a suppression of mononuclear cell synthesis of these proinflammatory cytokines when they are treated with IVIG.[13] The peripheral blood mononuclear cell production of TNF-α and IL-1, however, in patients with Kawasaki disease receiving IVIG therapy showed decreased synthesis of IL-1 but not of TNF-α.[177,178] The role of IVIG as an immunomodulator has been suggested in an ever-growing number of clinical disease states because of its broad immunoregulatory potential.[11,120] Its specific role in arresting proinflammatory cytokine activity, either directly or indirectly, warrants further clinical investigation.)

The hypothesis that diminished levels of cytokines may render a host susceptible to development of infection was introduced by Weatherstone and Rich.[280] They suggested that the increased susceptibility to infection observed in premature neonates may be secondary to deficient proinflammatory cytokine production. In their study, they measured cord blood monocyte secretion of TNF-α and IL-1 with and without stimulation of LPS. IL-1 activity by LPS-stimulated preterm monocytes did not differ from that observed by LPS-stimulated adult monocytes. TNF-α activity, however, in the LPS-stimulated monocytes from preterm neonates was significantly lower than that in both stimulated and unstimulated adult monocytes. Thus, they concluded that diminished production of TNF-α may predispose the preterm infant to acquisition of infection. This finding has not been supported by the studies of infected animals, which show markedly elevated TNF-α levels, and subsequent studies in preterm infants have not established a deficiency in TNF-α.[287] Williams and colleagues[287] and Peat and coworkers[227] have, in contrast, shown that mononuclear cells from term neonates produced enhanced levels of TNF-α in response to group B streptococci or endotoxin. Ongoing studies are defining the role of cytokine production in neonatal and other infections.

The proinflammatory cytokine IL-2 acts on activated T cells and to some extent on B cells and natural killer (NK) cells and causes them to proliferate or differentiate. IL-2 is synthesized by both T cells and NK cells.[207,278] Decreased IL-2 production or IL-2 receptor expression has been noted in a number of clinical disease states, most notably in cases of severe combined immunodeficiency disease. Lesser degrees of abnormalities may occur in acquired immunodeficiency syndrome (AIDS), type 1 diabetes mellitus, systemic lupus erythematosus, and hypogammaglobulinemia.[166,174,184] The most intriguing potential for IL-2 in the treatment of disease involves its use in tumor therapy.[242] IL-2 currently is approved for the treatment of metastatic renal carcinoma. Use of IL-2–activated NK cells results in a decrease in tumor burden in approximately 20 percent of patients, although serious side effects occur. In addition to its potential role as an antitumor agent, IL-2 shares many of the same effects as interferon-γ (IFN-γ) and may, someday, function as a therapeutic agent in infection, autoimmunity, and immunodeficiency.[174,242]

Both IL-8 and IL-9 have been investigated in various human disease states, primarily because of their powerful role in stimulating neutrophil function, including activation, adhesion, and chemotaxis. Patients with cystic fibrosis, bronchiectasis, and chronic bronchitis have demonstrated elevated levels of IL-8 in their sputum.[237] The sputum from these patients is highly chemotactic to neutrophils, but with treatment with monoclonal antibodies to IL-8, this chemotactic effect was inhibited. Aerosolized IL-8 inhibitors have been used in patients with cystic fibrosis and have resulted in decreased inflammation in these patients.[199,237] IL-8 inhibitors are being evaluated in infants with bronchopulmonary dysplasia. Researchers have speculated that the persistently elevated levels of IL-8 in the tracheal fluid of ventilated preterm infants lead to neutrophil accumulation and the development of pulmonary fibrosis, which may be reduced by IL-8 inhibitors.[143,154] Similar studies are being conducted with IL-9 inhibitors. Thus, these cytokines may play an important role in the acute inflammatory response leading to chronic disease states, and blocking of this response may be of therapeutic benefit. The proinflammatory IL-5 has not been implicated in a specific human disease state, but

its strong B-cell proliferative effects suggest that it has a possible role in the pathogenesis of immunodeficiency, and its potent effects on eosinophil production, activation, and migration implicate its action in allergic responses.[37]

The proinflammatory activities of IL-12 and IL-18 are of current immunologic interest as well. IL-12 is an integral immune regulator that is produced primarily by macrophages and dendritic cells.[222] IL-12 has been shown to induce the production of IFN-γ by T cells and natural NK cells.[192,193,222] IL-18 is another recently described cytokine with many proinflammatory functions.[201] IL-18 was defined initially as IFN-γ–inducing factor.[41,71,175] IL-12 and IL-18, both alone and in synergy, regulate IFN-γ production in response to infection with intracellular parasites and bacteria and in certain autoimmune diseases.* The regulation of these cytokines may be therapeutically beneficial in certain disease states.[77,107,196] The other proinflammatory cytokines also are in various developmental stages of experimental investigation. As we learn more about their specific actions, we will better be able to determine their use as potential immunomodulating agents.

The anti-inflammatory cytokines have limited clinical use. IL-4 can block both IL-1 and TNF-α transcription.[117,250] IL-4 has been shown to inhibit human neutrophil adhesion to human endothelial cells while enhancing the adhesion of eosinophils.[211] These effects have not been implicated in specific human diseases, but an IL-4 action is suggested in allergic responses. Although IL-6 has both anti-inflammatory and proinflammatory effects, the levels of this cytokine were found to correlate with mortality rates in children with gram-negative and gram-positive sepsis, suggesting that monitoring of IL-6 levels may be of prognostic value.[274] Similarly, IL-10 has been shown to block production of IL-1, IL-6, IL-8, IL-12, and TNF-α as well as GM-CSF in animal models.[63,194] It also has effects on mast cells, T cells, and NK cells, and it inhibits primary allogeneic T-cell responses. Thus, IL-10 may have a potential role in treating acute and chronic inflammation and may be effective in suppressing transplant rejection.[16,63] Studies examining the safety and immunomodulatory effects of the intravenous injection of IL-10 in humans demonstrate that it is well tolerated and results in decreased production of both TNF-α and IL-1.[27] Additional clinical studies have been conducted on the potential immunoregulatory effects of the anti-inflammatory cytokines, which may indicate their therapeutic use in human disease states.

Interleukin-17 (IL-17) is a recently described proinflammatory cytokine implicated in the regulation of many inflammatory states. IL-17 is produced by several cell types including activated T-cell subsets, NK cells, and neutrophils.[73,186,265] IL-17 is involved in the regulation of inflammatory bowel disease and systemic lupus erythematosus (SLE).[156] IL-17 production is markedly deficient in autosomal dominant hyper-IgE (Job syndrome) patients who have neutrophil chemotactic defects and suffer recurrent bacterial and candida infections.[168] More recently, decreased intracellular and extracellular production of IL-17 by cord blood mononuclear cells suggests IL-17 may contribute to the human neonates' increased susceptibility to microbial infections.[47,48] Furthermore, the addition of IL-17 to cord blood mixed mononuclear cells significantly enhances production of the proinflammatory cytokines IL-6, TNF-α, IL-1β, and IL-8 in response to group B streptococci.[47,48] IL-23 promotes the development and survival of IL-17 producing cells. The IL-17/IL-23 axis has been implicated in mediating initial neutrophil responses during infection. Dysregulation of this pathway is suggested in autoimmune diseases, i.e., multiple sclerosis, Crohn disease, and rheumatoid arthritis.[73,74,264] IL-17/IL-23 levels are elevated in Lupus patients and correlate with symptomatology.182,[291,294] Current efforts are under investigation to modulate the IL-17/IL-23 axis to regulate autoimmunity and inflammation.[148]

The removal of cytokines from blood of septic patients has received recent attention. The continuous removal of cytokines in the systemic inflammatory response syndrome by hemofiltration and hemodialysis is currently being utilized.[291] Cytokine adsorption has also received recent attention. The use of synthetic polymer resins,[146] immobilized antibody systems,[221] and activated carbon[10] is under investigation. The polymyxin B filtration system has been shown to protect mice from the endotoxin-induced shock[35]and is under investigation in adult patients with gram-negative sepsis in intensive care units.[61] These efforts to reduce the proinflammatory cytokine load may have a role in the treatment of septic shock.

Colony-Stimulating Factors

Colony-stimulating factors are involved principally in the production of neutrophils and monocytes. They were discovered because of their ability to stimulate the formation of colonies of granulocytes and monocyte-macrophages in cultured bone marrow cells and were named according to the primary cell colony type that they elicited. Granulocyte-macrophage colony-stimulating factor (GM-CSF) induces peripheral blood macrophages and granulocytes. It also has other pleiotropic effects, including stimulation of precursors of megakaryocytes, mast cells, and eosinophils. In addition, GM-CSF has effects on neutrophil migration and phagocytosis. Granulocyte colony-stimulating factor (G-CSF) induces peripheral blood granulocytes. Its actions are on both the production and function of neutrophils, including migration, phagocytosis, and superoxide generation. Macrophage colony-stimulating factor (M-CSF) induces peripheral mononuclear phagocytes. IL-3 increases mast cell populations as well as the induction of granulocytes, macrophages, eosinophils, and megakaryocytes.*

Clinical studies with GM-CSF and G-CSF as adjuvant therapy have been performed in individuals with distinct lymphopoietic disorders (i.e., congenital agranulocytosis, cyclic neutropenia, Shwachman-Diamond syndrome) or those due to the consequences of cytotoxic

*References 71, 77, 107, 128, 134, 145, 196, 223, 260, 264, 265, 275, 281, 295.

*References 72, 73, 110, 164, 175, 183, 205.

chemotherapy, AIDS, and aplastic anemia. The colony-stimulating factors can stimulate granulocyte and monocyte populations in these individuals, but the response is restricted to the number of available stem cells. Colony-stimulating factor treatment can partially or completely reverse congenital neutropenia and has shown great promise in regeneration of lymphopoietic cells after administration of cytotoxic chemotherapy and high-dose chemotherapy followed by autologous bone marrow transplantation. Recombinant human GM-CSF (rhGM-CSF) also has been shown to be beneficial in patients with aplastic anemia.[9,10,272] Hammond and colleagues[115] demonstrated a dramatic increase in neutrophil counts in children with cyclic neutropenia treated with recombinant human G-CSF (rhG-CSF). Cyclic neutropenia is a rare disorder characterized by regular 21-day cyclic fluctuations in the number of blood neutrophils, monocytes, eosinophils, lymphocytes, platelets, and reticulocytes. Although the exact mechanism of this disorder is not known, it is attributed to a regulatory abnormality affecting proliferation of stem cells. These infants have recurrent aphthous stomatitis, pharyngitis, lymphadenopathy, fever, and numerous infections during the periods of neutropenia. The length of cycling in treated infants decreased from 21 days to 1 day, and the neutrophil turnover rate increased nearly fourfold, significantly reducing the frequency of infection. Recombinant G-CSF also has shown promise for infants and children with neutrophil production disorders. Infants with congenital agranulocytosis, Kostmann syndrome, and Shwachman-Diamond syndrome, disorders characterized by severe, persistent absolute neutropenia, show a dramatic increase in neutrophil count after treatment with rhG-CSF.[26] In addition, rhG-CSF and rhGM-CSF have been used in neutropenic patients with AIDS. Despite the concern that the effects of GM-CSF to activate macrophages may in turn promote replication of human immunodeficiency virus (HIV), current studies are defining the role of rhGM-CSF and rhG-CSF in patients with AIDS.[109,183]

Thus, colony-stimulating factors have emerged as significant modulators of human immune function and lymphopoiesis. Because the colony-stimulating factors can functionally activate mature granulocytes and monocytes, considerable attention has focused on their future role in treating individuals at risk for acquiring infection. English and colleagues[76] reported decreased GM-CSF production by neonatal T cells. Because a major factor contributing to the increased susceptibility of human neonates to severe infections is their inability to produce adequate numbers of neutrophils in response to bacterial infections, these neonates may benefit from colony-stimulating factor treatment during severe infection.[22] Similar treatment in immunologically stressed burn and trauma patients also may prove beneficial.[65,219]

INTERFERONS

Interferon-α and Interferon-β

The interferons are glycoproteins that were discovered because of their antiviral properties. They are known to possess antitumor and immunomodulatory activities in addition to their antiviral effects.[12] The interferons have been classified into three major groups: α, β, and γ. IFN-α and IFN-β were previously known as type I interferon and have similar protein structures and bind the same receptor. IFN-γ, formerly type II interferon, has a much different structure and its own receptor.[8] IFN-α is produced by leukocytes. The earliest demonstration of its clinical usefulness was in the treatment of AIDS-related Kaposi sarcoma. In these initial studies, a Kaposi sarcoma tumor response occurred in 30 to 50 percent of the patients treated with recombinant IFN-α.[108,161,209,213] Researchers have speculated that IFN-α exerts its antitumor effect by activating cytotoxic T cells. Since then, placebo-controlled clinical trials have shown that IFN-α also may have significant antiretroviral effect in HIV-infected patients.[159,172] Clinical trials have been conducted to determine the effect of early treatment with IFN-α in reducing progression of HIV disease and to determine the therapeutic effect of IFN-α in combination with other drugs in the treatment of HIV infection and HIV-related diseases.[158,160]

IFN-α also has been used in various parts of the world for the treatment of chronic myeloid leukemia, hairy-cell leukemia, basal cell carcinoma, multiple myeloma, hepatitis B and C, and condylomata acuminata (genital warts). In chronic myeloid leukemia, early treatment with IFN-α has been reported to elicit complete hematologic remission in more than 70 percent of the patients treated. Many of these patients had total elimination of the Philadelphia chromosome, which is a hallmark of the disease.[266-268] Complete to 80 percent remissions also have been reported in the treatment of hairy-cell leukemia.[232] Intralesional injection of IFN-α into basal cell carcinoma of the skin resulted in 81 percent tumor remission as determined by biopsy.[57,139] Despite the variability of the outcomes among reports on the use of IFN-α in the treatment of multiple myeloma, it has been approved as a therapy for these patients in a number of European countries.[195]

IFN-α also is used for the treatment of hepatitis B and C.[175] Clinical responses have been reported to be of long duration, often with complete loss of both hepatitis B surface antigen and evidence of viral replication. In chronic hepatitis C, complete responses to therapy determined by the decline of serum aspartate aminotransferase to normal levels have been observed in 50 to 70 percent of the patients treated. Although serum aspartate aminotransferase levels in half of the patients who had improved returned to pretreatment levels within 6 to 12 months after discontinuation of therapy, nearly 20 percent achieved sustained remission.[66,69,133,155,228] Studies also have shown that IFN-α is useful in treating condylomata acuminata caused by papillomaviruses.[34] Intralesional injections of IFN-α completely eliminated warts in more than 50 percent of the patients treated. IFN-α therapy also is suggested to reduce the number of lesions in juvenile laryngeal papillomatosis after systemic use.[190] Thus, IFN-α has therapeutic potential as both an antitumor and an antiviral agent.

IFN-β also has received attention as an antiviral and antitumor agent. Its clinical usefulness as a single-agent

therapy is suggested in relapsing multiple sclerosis. The mechanism of IFN-β therapeutic action in multiple sclerosis is unknown.[140] Ongoing studies are investigating IFN-β therapy in combination with IFN-α in the treatment of various malignant neoplasms.

Interferon-γ

IFN-γ is produced by $CD4^+$ and $CD8^+$ cells as well as by NK cells.[122] Investigators have reported that circulating mononuclear cells and T cells from neonates are markedly deficient in their ability to produce IFN-γ in response to a variety of stimuli, compared with adult cells.[182,252,253,288] Studies using recombinant IFN-γ have shown that preincubation of neonatal neutrophils, which are deficient in their chemotactic ability, with recombinant IFN-γ enhances their chemotactic response to a level equal to that of adult neutrophils.[108] Other studies have shown that neonatal mixed mononuclear cells are deficient in the production of the IFN-γ–stimulating cytokines IL-12 and IL-18 in response to GBS.[126,128,144] In vitro treatment with recombinant IL-12 and IL-18 can correct this defect in IFN-γ production in response to GBS. These findings suggest that a potential role exists for the regulation of IFN-γ in neonatal host defense.

Job syndrome was first described by Davis, Schaller, and Wedgwood[67] in 1965 in two patients with recurrent staphylococcal abscesses. Patients with this syndrome often develop chronic sinopulmonary infections and mucocutaneous *Candida* infections. Hill and coworkers[129] observed that the patients with Job syndrome also have a profound defect in neutrophil chemotactic responsiveness along with extreme hyperimmunoglobulin E. This defect in neutrophil chemotaxis is intermittent and occurs predominantly when the patient is symptomatic.[64,123,129] Because production of IFN-γ by mononuclear leukocytes in patients with hyperimmunoglobulin E is markedly deficient or absent, in vitro studies were conducted to determine the effect of recombinant IFN-γ on the chemotactic responsiveness of neutrophils from patients with this syndrome. After pretreatment with IFN-γ, the chemotactic response of the neutrophils from patients with Job syndrome increased significantly, with an average enhancement of 300 percent above baseline to levels not significantly different from those of matched healthy controls.[142,295] In four patients with Job syndrome, preliminary trials of IFN-γ therapy with hyperimmunoglobulin E suggested clinical benefit in three, with a significant decrease in eczema as well as in pulmonary symptoms and secretions.

Patients with chronic granulomatous disease (CGD) have an inherited deficiency in the proteins required for nicotinamide adenine dinucleotide phosphate oxidase activity. Phagocytes with this enzymatic defect are able to engulf bacteria but cannot generate the respiratory burst necessary to kill the organisms. Consequently, patients with CGD suffer severe chronic, recurrent life-threatening infections. The usefulness of treating CGD patients with IFN-γ was suggested by studies showing that this lymphokine can stimulate the respiratory burst of normal phagocytes. Results of studies by Ezekowitz and colleagues[80] and Sechler and coworkers[251] showed that when macrophages from patients with CGD were treated with IFN-γ in vitro, a respiratory burst occurred and superoxide anion was generated. Sechler and colleagues[251] further demonstrated a partial correction in neutrophils and monocytes from patients with CGD after subcutaneous treatment with recombinant IFN-γ. These initial results suggested that when it is administered in vivo to patients with CGD, recombinant IFN-γ could partially correct the defective ability of phagocytes to kill bacteria. Ezekowitz and coworkers[81,122] extended these findings in a double-blind placebo-controlled trial. They showed that recombinant IFN-γ significantly decreased the relative risk for development of serious infection in patients with CGD, but these studies failed to demonstrate an effect of IFN-γ on respiratory burst activity. This cytokine most likely affects the arginine–nitric oxide pathway in neutrophils and macrophages. Patients who received IFN-γ had a 70 percent reduction in the risk for development of serious infection compared with controls. Overall, IFN-γ decreases the risk for development of infection and the duration of hospitalization in patients with CGD. When it is administered with prophylactic antibiotics, an additive effect occurs, resulting in a nearly 20 percent increase in the infection-free rate of patients with CGD compared with IFN-γ alone.[81] IFN-γ was licensed by the U.S. Food and Drug Administration in December 1990 for the treatment of patients with CGD. The authors of the collaborative studies recommended its use with the addition of prophylactic antibiotics for treatment of patients diagnosed with CGD.[97]

TOLL-LIKE RECEPTORS

Toll-like receptors (TLRs) are pathogen pattern-recognition receptors central to innate immune responses.[141] TLRs are a family of type 1 integral membrane glycoproteins that detect pathogens and initiate cytokine production by activation of nuclear factor κB (NF-κB). The ligands recognized by TLRs consist of a wide range of evolutionarily conserved motifs, such as LPS, single- and double-stranded RNA, and zymosan. Collectively, these motifs are called pathogen-associated molecular patterns (PAMPs). TLR recognition of PAMPs contributes to the immediate response and broad specificity of innate immune recognition toward bacterial, viral, fungal, and parasitic pathogens. Twelve TLRs have been described in mammals, with at least 10 known in humans.[2,3,6]

The role of TLRs as immunomodulating agents is of contemporary interest. Amlie-Lefond and colleagues[5] described the potential use of TLR agonists as protective agents against biothreat pathogens. TLRs 1 to 10 in humans act to augment the immune response. TLR agonists can bolster this response and potentially offer protection against specific infections or diseases. Stimulation of TLR-7 and TLR-8 has shown antiviral and antineoplastic properties in humans. A drug known to do this, imiquimod (Aldara), has been shown to be beneficial against human papillomavirus, molluscum contagiosum, genital warts, and basal cell carcinoma.[5,58,269]

Immunomodulatory oligonucleotides stimulate Toll-like receptors and induce cytokine production. Immunomodulatory oligonucleotides offer potential clinical use for treatment of a number of inflammatory diseases, including severe acute respiratory syndrome, for which clinical trials are under way.[5] Similar use of immunomodulatory oligonucleotides in patients with renal carcinomas and HIV infection also is under investigation. Recent evidence suggests that TLR-3 activation can enhance innate immune response and enhances production of IFN-α.[162] These features render TLR-3 agonists attractive agents in the treatment of HIV-related infections and infections in certain immunocompromised patients.

TLR expression in human neonates is currently being defined.[244] TLR-2, TLR-4, and TLR-8 functions have been described in neonates. Researchers have speculated that deficiency of TLR activation may contribute to the neonate's increased susceptibility to infection.[276] The results of TLR expression in neonates have varied. In general, similar expression of TLRs 1 to 4 occurs in neonates and adults. Low-birth-weight or premature infants, however, demonstrate significantly decreased expression of TLR-4.[92,269] Most studies describe decreased cytokine production to TLR agonists in neonates compared with adults. Caron and colleagues[165] reported significantly lower LPS stimulation of TLR-4 in neonates compared with adults and speculated that this decreased stimulation may contribute to the neonate's increased susceptibility to *E. coli* and other gram-negative infections.[165] Similarly, Levy and colleagues[181] demonstrated that TLR-8 agonists are beneficial in activating costimulatory responses in neonatal antigen-presenting cells and suggested that this type of agent may be used adjuvantly to enhance the neonatal immune response.

NEUTROPHILS AND COMPLEMENT

Recruitment of neutrophils from the bloodstream to extravascular sites of inflammation is a critical event in host defense against bacterial infection and in the repair of tissue damage. Under certain circumstances, accumulation of neutrophils may contribute to vascular and tissue injury. Thus, the regulatory mechanisms involved in neutrophil activation, recruitment, and subsequent degranulation are of potential clinical significance. Neutrophil adherence to and migration through capillary endothelium is a critical early event in the acute inflammatory response. The adhesive interactions between leukocytes and endothelial cell surfaces are regulated by two novel families of glycoproteins: the integrins and the selectins. The β_2 integrins are membrane-bound glycoprotein receptors found on the surface of PMNs. The β_2 integrins CD11 and CD18 are required for adherence of PMNs to endothelial cell surfaces. The selectins also are membrane-bound glycoproteins that mediate neutrophil adhesion to endothelial cells. They include L-selectin, which is found on the surface of PMNs, and P-selectin and E-selectin, which are expressed on the surface of activated endothelial cells.[21,46,261,283,300]

The interaction between the β_2 integrins and the selectins serves to regulate PMN responses during inflammation. In general, the selectins P and E on the activated endothelial cell surface and L-selectin on the PMN cell surface function to facilitate PMN rolling and tethering to activated capillary endothelium. Once this tethering has occurred and the PMN itself is activated, the β_2 integrin CD11/CD18 receptors on the PMN form a tight adhesion with the endothelial cell surface, which facilitates PMN attachment and polarization, leading to migration.[21,46,261,300] Congenital β_2 integrin CD11/CD18 deficiency states have been described (leukocyte adhesion deficiency type I). These patients have profound PMN adhesion and motility defects and recurrent life-threatening infections along with delayed separation of the umbilical cord and juvenile periodontitis.[79,96] A second type, leukocyte adhesion deficiency type II, has been described as being due to a deficiency of sialyl Lewis^X, the PMN ligand for E-selectin on endothelial cells.[225,229] Researchers also have shown that the tethering of PMNs to P-selectin on activated endothelial cells is critical for PMN priming by platelet-activating factor and that monoclonal antibodies to P-selectin can block this response.[187] Monoclonal antibodies to P-selectin have been used in animal models of ischemia and reperfusion injury and have been shown to reduce significantly the severe edema and endothelial cell injury observed after reperfusion.[289] Similarly, monoclonal antibodies to P-selectin have resulted in significant endothelial cell preservation in animal models of lung injury and cardiac ischemia.[212,284] Monoclonal antibodies to E-selectin and L-selectin also are being tested in animal models.[200] With the rapid advancements occurring in identification of new molecules that influence endothelial cell–leukocyte interactions, we will gain greater understanding of the complexity of cellular communication during inflammation.

BACTERICIDAL/PERMEABILITY-INCREASING FACTOR AND DEFENSINS

In addition to their respiratory burst activity in antimicrobial defense, human neutrophils have been shown to contain a variety of granule-associated antibacterial proteins and peptides.[258] These include bactericidal/permeability-increasing protein (BPI) and the defensin family of peptides. BPI is a 55-kDa receptor present in neutrophil granules, which contain two domains. One of the domains binds with LPS to increase membrane permeability and the lysis of gram-negative bacteria, whereas the other promotes the opsonization of gram-negative bacteria.[131] Neutrophil BPI functions best in inflamed tissues, where it acts in concert with defensins and the membrane attack complex of complement to cause cell lysis.

Meningococcemia is a severe gram-negative infection that occurs predominantly in infants and young adults. Mortality rates of meningococcemia range from 10 to 20 percent.* Endotoxin levels may be profoundly elevated

*References 8, 32, 119, 285, 292, 299.

and correlate with the severity of the illness.[30] Recombinant BPI (rBPI) has been used as an adjunct to antimicrobial therapy in children with severe meningococcal sepsis[179]; 14 of 193 patients with severe meningococcal disease who received rBPI (2 mg/kg during 30 minutes) died, compared with 20 of 203 control infants, an insignificant difference. Among the surviving treated patients, however, a modest improvement was noted in long-term functional outcome, suggesting a possible beneficial effect in decreasing complications associated with septic shock.[102,179] Neonates have been shown to have reduced release and activity of BPI, which may contribute to their enhanced susceptibility to gram-negative bacterial infections.[180]

The defensins are strongly cationic, single-chain peptides contained in neutrophil primary, or azurophilic, granules with molecular weights between 3 and 4.5 kDa. Defensins comprise 50 percent of the protein content of the neutrophil primary granules.[98,296] These peptides possess broad antimicrobial activity against gram-positive and gram-negative bacteria, fungi, mycobacteria, and some viruses. The defensins create voltage-sensitive pores in microbial membranes, resulting in cell lysis. They are divided into α and β defensins. Humans have six human α defensins (HAD-1 to HAD-6) and two human β defensins (HBD-1 and HBD-2).

The α defensins, HAD-1 to HAD-6, are made by neutrophils and compose 30 to 50 percent of the primary granule content.[118] Defensins appear at the site of inflammation. They are present after neutrophil degranulation induced by LPS, IL-8, C5a, and other stimuli. They also are found on the epithelial surfaces of the bronchi and in bronchial lavage fluid of patients with various types of inflammatory lung disease. The antimicrobial activity of the defensins is inhibited by high salt content, which may be clinically important in the immune response of patients with cystic fibrosis.[105]

The β defensins are produced by epithelial cells of the respiratory and gastrointestinal tracts.[24,253] HBD-1 is expressed constitutively by epithelial cells in the bronchi and the intestine, whereas HBD-2 synthesis is upregulated by inflammatory stimuli, including LPS, TNF-α, bacterial infection, and injury. Thus, HBD-1 acts to kill organisms in the absence of inflammation, whereas HBD-2 acts primarily as part of the inflammatory process.

In inflammatory lung disease, such as chronic bronchitis and chronic obstructive lung disease, both α defensins HAD-1 to HAD-6 and β defensin HBD-2 may be increased significantly, perhaps contributing to airway inflammation.[296] There are no reported clinical disorders of defensin production. Potential roles for the defensins as immunoregulatory-antimicrobial agents are being investigated.

Endotoxin and other proinflammatory mediators activate the complement system and the chemotactic properties of C5a, which recruits neutrophils to sites of infection. Interruption of this process at various levels may be possible with use of monoclonal antibody strategies that counteract the effects of the complement leading to septic shock. Although monoclonal antibodies directed at the specific components of the complement cascade have not been tested in human clinical trials, the use of monoclonal antibodies to inhibit C5a in primates challenged with *E. coli* improved the survival rate and reduced the incidence of adult respiratory distress syndrome.[7,25]

PLATELET-ACTIVATING FACTOR

Platelet-activating factor (PAF) is a potent phospholipid inflammatory mediator with many biologic effects. Its synthesis is regulated by phospholipase A_2, an enzyme associated with the arachidonic acid pathway. PAF has a very short half-life in vivo because of its rapid degradation by PAF acetylhydrolase. PAF is synthesized by many cell types, including macrophages, neutrophils, platelets, eosinophils, endothelial cells, and hepatocytes.[286] Intravenous infusion of PAF into animals results in pulmonary hypertension, bronchoconstriction, neutropenia, thrombocytopenia, and ischemic bowel necrosis.[17,52,116] Production of PAF is stimulated in numerous clinical disease states, including hypoxia and ischemia, and after administration of biologic agents such as LPS, GM-CSF, TNF-α, IL-1, bradykinin, and thrombin.* Corticosteroids decrease levels of PAF by the induction of its natural inhibitor, PAF acetylhydrolase.[106] PAF has been shown to stimulate the production of many other mediators of inflammation, including TNF-α, complement breakdown products, oxygen radicals, catecholamines, prostaglandins, thromboxane, and the leukotrienes.† It also activates endothelial cells and neutrophils and monocytes, leading to their adherence and migration.[202] Thus, PAF is a ubiquitous phospholipid mediator with many biologic effects and interactions within the inflammatory cascade.

The regulation of PAF has been studied in numerous potential clinical disease states, including sepsis and septic shock.[135] In the clinical phase III trials in septic patients and patients in septic shock who received a PAF antagonist, a significant reduction in the mortality rate was noted.[68] The role of PAF, however, in the pathogenesis of necrotizing enterocolitis (NEC) has received considerable recent attention.[43,44] NEC often is a fatal gastrointestinal disease that predominantly affects premature infants. Exogenous administration of PAF into rat mesenteric circulation causes ischemic bowel necrosis and disease similar to that seen in neonatal NEC.[136] Endotoxin-induced intestinal injury is associated with increased PAF levels, and the infusion of high doses of endotoxin into animals produces a similar pathologic model of NEC, which can be prevented by administration of dexamethasone, PAF acetylhydrolase, or PAF receptor antagonists.[42,138] These animal studies suggest a link between PAF and its regulation and the development of NEC and implicate PAF as a potential endogenous inflammatory mediator in the pathogenesis of neonatal NEC.

Evidence in humans supports an association between PAF and human neonatal NEC. PAF levels are higher in infants with NEC compared with controls, and PAF

*References 83, 163, 203, 204, 230, 242, 290.
†References 85, 137, 163, 241, 273, 299.

acetylhydrolase activity is lower in infants with NEC.[45] PAF acetylhydrolase is suppressed with prematurity.[41] Because enteral feedings are necessary for the development of NEC, PAF levels were measured in feeding premature infants. In these studies, feedings alone increased circulating PAF levels but not PAF acetylhydrolase, and infants fed human breast milk had lower PAF levels and a lower incidence of NEC, suggesting a protective effect of human milk through PAF regulation.[191] Human milk is known to have a number of factors protective against infectious disease, including PAF acetylhydrolase.[38,104] Because PAF acetylhydrolase activity is present in human milk and absent in formulas, the suggestion has been made that the protective activity observed in human milk against the development of NEC may result from blocking of PAF-related inflammatory responses.[38] The modulation of the many interactions of PAF within the inflammatory cascade may have future clinical potential in regulating neonatal NEC and other inflammatory disease states.

NITRIC OXIDE

Nitric oxide is a membrane-permeable gas that functions in the regulation of vascular tone and in the inhibition of platelet aggregation and leukocyte adhesion. In addition, nitric oxide has been shown to have antitumor as well as antimicrobial activity. Under normal conditions, nitric oxide synthase induces endothelial cell production of nitric oxide. The signal transduction pathway for nitric oxide is linked to pathways involving vasodilation. Some evidence indicates that the L-arginine–nitric oxide pathway is activated in sepsis, in which the effects of nitric oxide on the vasculature are associated with the severe vascular failure observed during septic shock.* Thus, inhibition of production of nitric oxide has been proposed as a novel approach for the treatment of the severe hypotension associated with septic shock.[279]

The increased production of nitric oxide observed during septic shock may have several harmful effects. Nitric oxide may be largely responsible for sepsis-induced hypotension. In vitro studies implicate nitric oxide in sepsis-induced myocardial depression, although nitric oxide synthase inhibitors have not been shown to prevent endotoxin-induced myocardial depression in vivo. Nitric oxide also has direct cytotoxic effects, and its overproduction in septic shock can lead to tissue injury and organ failure.[55,86,150] In addition, in vitro experiments suggest that nitric oxide may enhance the release of proinflammatory cytokines during septic shock.[78,217] Production of nitric oxide may, however, have some beneficial effects during septic shock. It is implicated in maintaining visceral and other microvasculature blood flow, both as a counterregulatory mechanism to the vasoconstrictive mediators released during sepsis and by its ability to block platelet adhesion, reducing potential microvasculature stasis and thrombosis.[151,198] In addition, high levels of nitric oxide have antimicrobial activity and enhance LPS-induced production of cytokine,[164] although whether these levels of nitric oxide reflect actual physiologic states has yet to be determined.

Because hypotension during sepsis is an important predictor of organ injury and death, use of nitric oxide synthase inhibitors may improve survival in severe septic shock by increasing mean arterial pressure. Nitric oxide synthase inhibitors have been shown to restore vascular responsiveness to catecholamines in animal models of endotoxin-induced septic shock.[132] In addition, nitric oxide synthase inhibition has been shown to normalize mean arterial pressure in anesthetized animals challenged with endotoxin or TNF-α without causing hypertension.[150] These considerations have led to the use of nitric oxide synthase inhibitors to treat hypotension in patients with sepsis and in those receiving cytokine therapy for cancer.[149,188] Although these agents can alter mean arterial pressure, beneficial effects on clinical outcomes, including survival, are only suggested in human clinical trials.[217] Studies of endotoxin-challenged rats showed that partial nitric oxide synthase inhibition improved survival, whereas complete inhibition of nitric oxide production clearly is harmful, suggesting a beneficial effect with selective partial nitric oxide inhibition. Studies of nitric oxide inhibition that is more selective are being explored, and in the future such therapy may have clinical utility in the treatment of infectious disease states.

CONCLUSION

The initial attempts to augment immune function in the treatment of sepsis consisted of serum antibody therapy. The development of and refinements in hybridoma and recombinant technologies have provided the means to generate highly specific monoclonal antibodies. Although monoclonal antibodies directed toward bacteria and their components currently are not used during a course of sepsis, their future may be in combination with antimicrobial pharmacologic agents to treat infections with certain pathogens. The recent advances in basic science and clinical research also have demonstrated that the cytokine family plays many crucial roles in the pathogenesis of septic shock. The interaction among the proinflammatory cytokines initiates the development of a cascade of biologic events leading to the propagation and regulation of inflammation. Although the proinflammatory cytokines are effective in augmenting immune responses, their overexpression can lead to severe septic shock. The use of neutralizing monoclonal antibodies to endotoxin, anti–TNF-α antibodies, and soluble TNF-α and IL-1 receptors as well as IL-1 receptor antagonists in human clinical trials of septic shock, however, has shown limited therapeutic potential. The future clinical use of cytokine inhibition may include a combination of a number of both recombinant and pharmacologic agents temporally administered to regulate multiple proinflammatory cytokine–mediated steps in the development of septic shock. The hematopoietic growth factors have demonstrated considerable clinical effect, especially in individuals with distinct lymphopoietic disorders and in patients receiving immunosuppressive chemotherapy.

*References 55, 56, 152, 210, 217, 218.

The interferons α, β, and γ have received considerable attention during the past decade as potential immunomodulators. IFN-α has shown broad clinical application as an antitumor agent as well as an antiviral agent; IFN-β is being used with some success in patients with relapsing multiple sclerosis. The stimulatory effect of IFN-γ on human neutrophils is demonstrated in infants and children with specific neutrophil disorders and in neonatal sepsis. Toll-like receptor agonists are emerging as attractive therapeutic agents in a number of infectious diseases. Investigations defining the actions of the integrins and the selectins, bactericidal/permeability-increasing factor and defensins, and platelet-activating factor and nitric oxide may provide novel future clinical therapeutic approaches to attenuate acute inflammatory responses. As we learn more about the complexity of intracellular and extracellular interactions and the delicate balance these molecules have in regulating immune responses, we will be better able to implement their clinical use in regulating infectious disease states in infants and children.

CHAPTER 242

Probiotics

Gail J. Harrison

This chapter is a general overview of the topic of probiotics, synbiotics, prebiotics, and postbiotics, and their application to prevention and treatment of disease in newborns, infants, and children.[4] The concept of probiotics may date back to the turn of the 20th century, in 1908, when Eli Metchnikoff observed that the longevity of Bulgarian peasants may have been linked to their diet, which included consumption of fermented milk. The term *probiotic* was probably first used scientifically in 1965 when Lilly and Stillwell described substances produced by one microorganism that stimulated the growth of another microorganism. *Lactobacillus rhamnosus* GG (LGG), derived from the *Lactobacillus* strain used for fermentation of dairy products, was likely the first probiotic used clinically, and remains the probiotic used most commonly in clinical studies and clinical medicine.

Increasing evidence from basic and translational research has shown that the timing and type of intestinal microflora colonization influences the development of immune function and is highly influenced by the infant's early diet and intestinal microbial environment.[38,39] Probiotic bacteria, postbiotic bacterial by-products, and dietary prebiotics likely exert positive effects on the development of the immune system during infancy and through competitive inhibition may prevent colonization of potential enteric pathogens. Colonization with nonbeneficial bacteria and exposure to antimicrobial agents in the newborn period may result in immune dysregulation and disorders of immune function. Disturbances in the gut microbial composition may play a role in the pathophysiology of a variety of disorders by modulating immune programming. The "hygiene hypothesis" suggests the reduction in general microbial exposure during early childhood may play an important role in modifying the early composition of gut microbial flora, with benefit to the host by reducing risk for infection and allergic disease. These research findings have led to clinical trials evaluating the role of these products in clinical medicine. The clinical effects of prebiotics and probiotics have varied in clinical trials, most likely because the influence of probiotics is a complex process, and varies with type, strain, dose, viability, timing, duration, adherence to regimen, other dietary restrictions, and method of administration evaluated for each different clinical condition within each clinical trial. Although not strictly antimicrobials in the classic sense, these biotic products may help provide additional defense against infectious diseases and are used widely in both developed and developing countries to improve the health and well-being of infants and children.

DEFINITIONS

Probiotics is a general term for different strains and species of microorganisms, usually commensal living bacteria of mammalian microbiota, with a wide range of clinical and immunologic uses.[4,12] The term is derived from Greek, meaning "for life." The United Nations Food and Agricultural Organization and the World Health Organization have defined probiotics as "live microorganisms, which, when administered in adequate amounts confer a health benefit on the host." Probiotics considered as oral supplements, additives, or food products are marketed as dietary supplements and do not require premarket review and approval by the U.S. Food and Drug Administration (FDA). However, probiotics or prebiotics that are marketed specifically for the treatment or prevention of a specific disease or condition are classified as biologic products and, thus, require FDA review and approval. The most commonly used probiotics include bacteria that are fermentative, anaerobic, and nonmotile and produce lactic acid. They are thought to generate small molecular metabolic by-products, such as short-chain fatty acids, sometimes called *postbiotics*, that may function as immune modulators. Probiotics are usually species of the bacteria *Lactobacillus*, *Bifodobacterium*, or *Streptococcus* or the yeast *Saccharomyces* (Table 242-1). Probiotic preparations may be administered as a single strain or a mixture of different types of bacteria or yeast.

Probiotics may influence immune function through their effects on local immunity and stabilization of intestinal barrier integrity.[17] Probiotics are generally regarded as safe for administration to otherwise normal infants, children, and even pregnant women, and they are available in many food products, such as live culture yogurt. Human breast milk also may naturally contain probiotics from maternal sources. Probiotics may be given separately like a medicine or supplement, mixed with or added to a naturally existing food, or even added to infant formula or human breast milk.[28] However, probiotics may stimulate growth of gut bacteria and cause deleterious metabolic activity, excessive immune stimulation, and even systemic infections. Therefore, preterm neonates, children with short bowel syndrome, immunocompromised patients, and other special hosts, should receive probiotics only after careful consideration and observation and careful weighing of potential benefits and risks.[38]

Prebiotics are nondigestible food ingredients added as supplements to food or infant formulas. Human breast milk contains many natural prebiotics.[12] Prebiotics used as supplements usually are oligosaccharides and include

TABLE 242-1 Commonly Used Probiotic Microorganisms for Prevention and Treatment of Disease

Bacteria

Lactobacillus
L. acidophilus
L. bulgaricus
L. caseii
L. fermentum
L. paracasei
L. plantarum
L. rhamnosus (GG)

Clostridium butyricum

Yeast
Saccharomyces boulardi

fructo-oligosaccharides (FOS), inulin (a group of FOS), galacto-oligosaccharides (GOS), soybean oligosaccharides, lactulose, and dietary fibers. They are a major substrate for bacteria and are designed to promote and stimulate the growth of beneficial, indigenous strains of bacteria, especially *Bifidobacterium* spp. The effects of prebiotics are potentially broader than a single probiotic strain of bacteria. The fermentation by-products of prebiotics also produce short-chain fatty acids that may have an anti-inflammatory effect and may directly affect the mucosal and systemic immune systems. A theoretical concern is that prebiotics may promote growth of potential pathogens or encourage growth of commensal bacteria that may translocate across the gut epithelial barrier in the preterm neonate with immature gut or in an immunocompromised host with altered immunity. In the otherwise normal older infant and child, prebiotics have not shown adverse effects, have appeared safe to administer, and have even been added to some infant formulas.[28]

Synbiotics are a combination of prebiotics and probiotics that may produce a synergistic beneficial effect.[12] The combination of both prebiotic dietary carbohydrates that escape digestion and probiotic bacteria appears to improve the survival of the probiotic bacteria in the gastrointestinal tract, and enhances their effect in certain circumstances.

USE OF PROBIOTICS AND PREBIOTICS FOR PREVENTION AND TREATMENT OF CLINICAL CONDITIONS

Gastrointestinal Disorders

Acute Infectious Diarrhea

Randomized clinical trials have shown benefit in giving probiotics, mixed with human or cow milk or formula or given as a separate oral supplement, to prevent acute gastroenteritis in healthy infants and children, especially if they attend group child-care settings, and especially if the cause of the gastroenteritis was rotavirus.[5,11,16,37] A variety of probiotic preparations have been studied and shown to be beneficial in preventing infectious viral diarrhea, including *L. rhamnosus* LGG, *Streptococcus thermophilus*, *Lactobacillus casei*, *Lactobacillus reuteri*, and *Bifidobacterium lactis*.[34,37,38] Randomized clinical trials have also shown probiotics have therapeutic benefit for treatment of acute infectious diarrhea, especially acute rotavirus diarrhea in otherwise healthy infants and children.[16,23] Probiotics, when administered early in the illness, reduce the number of diarrheal stools per day, shortens the duration of diarrhea by 1 day, and shortens the time for intravenous fluids needed for rehydration (Table 242-2).

Antibiotic-Associated Diarrhea

Antibiotic-associated diarrhea (AAD) or AAD associated with *Clostridium difficile* may occur in approximately one third of patients treated with antibiotics and may reduce compliance or adherence with antibiotic treatment regimens or cause significant morbidity. Randomized clinical trials have shown a prophylactic beneficial effect when a probiotic, when added to infant formula or taken as a separate supplement, was started at the same time antibiotic treatment was initiated.[3,14,18,19,20] The probiotics most commonly used to prevent AAD, including *C. difficile* AAD, include *L. rhamnosus* LGG, *B. lactis*, *S. thermophilus*, and *Saccharomyces boulardii*.[19,30,33,38] The clinical trial data to support the use of probiotics to treat AAD or AAD associated with *C. difficile* in children, however, are currently lacking, and the routine use of probiotics for treatment of AAD in children, at this time, is not routinely recommended.[19,34]

Gastritis Caused by Helicobacter pylori

Randomized clinical trials have shown clinical benefit for probiotics to improve eradication of *H. pylori* infection.[34] Therefore, it is often used as adjunctive therapy for *H. pylori*–associated gastritis in both adults and children.

Inflammatory Bowel Disease

Probiotics are commonly administered as adjunctive treatment for inflammatory bowel disease (IBD). The administration of probiotics in both adults and children with chronic ulcerative colitis and with pouchitis

complicating ulcerative colitis have shown beneficial effects.[29] The probiotics most often used in clinical trials showing benefit for treatment of ulcerative colitis include *S. thermophilus* and *Lactobacillus* and *Bifidobacterium* spp., as well as *Escherichia coli* Nissle 1917. As yet, no proven benefit supporting probiotics for treatment of adults or children with Crohn disease has been demonstrated.[34]

Irritable Bowel Syndrome, Constipation, and Infant Colic

Probiotics have been shown to benefit children with irritable bowel syndrome by reducing abdominal distention and pain.[34,38] However, probiotics have not been shown to significantly improve functional constipation in children at this time. A positive therapeutic effect has also been shown when a probiotic containing *L. reuteri* was administered to infants with colic who were exclusively breast-fed. The benefit of probiotics to treat colic in formula-fed infants has not been convincingly demonstrated at this time.

Hepatic Encephalopathy

The potential benefits of probiotics administered to patients with hepatic encephalopathy from liver failure have been investigated in several clinical trials.[15,25] Probiotics appear to reduce plasma ammonia concentrations, but have not been shown consistently to be efficacious in improving clinically relevant outcomes, such as decreased incidence of sepsis, shorter duration of hospital stay, and improved mental functioning.

Allergic and Atopic Diseases

In one randomized clinical trial, a probiotic containing *L. rhamnosus* LGG, when administered to pregnant women in the final month of pregnancy and to lactating mothers and their breast-fed infants for 6 months after birth, significantly reduced the frequency of atopic eczema.[8,9,32,41] In one clinical trial, prebiotics containing oligosaccharides FOS and GOS administered to infants at risk for atopic diseases, a reduced incidence of eczema, recurrent wheezing, and allergic urticaria.[41] In addition, use of probiotic containing *Lactobacillus fermentum* administered to children with atopic dermatitis showed improvement in contrast to placebo. However, even though these findings were encouraging, they have not been confirmed in other clinical trials at this time. Therefore, experts differ in their recommendations regarding use of probiotics and prebiotics for treatment and prevention of allergic and atopic diseases.[38,41]

Upper and Lower Respiratory Tract Infections

Probiotic *L. rhamnosus* LGG, when administered to young children up to 6 years of age, may reduce the incidence of upper respiratory tract infections and the common cold, but has not been shown to be beneficial for prevention or treatment of established lower respiratory tract infections such as pneumonia in older children.[13,21] In one very recent study, synbiotics containing *Lactobacillus planatarum* and FOS oligosaccharides administered to neonates and young infants in developing countries reduced incidence of lower respiratory tract infections, including radiographically proved pneumonia requiring treatment with antibiotics.[31]

Neonatal Sepsis and Necrotizing Enterocolitis

Probiotics offer potential benefits for newborns, including premature infants.* Probiotic administration has been shown in randomized clinical trials to reduce incidence of necrotizing enterocolitis (NEC), as well as mortality from NEC in neonates, including preterm neonates.† A variety of different probiotics in single-organism formulations and combination mixtures have been evaluated, including *L. rhamnosus* LGG, *B. bifidus*, *Bifidobacterium*

*References 7, 26, 35, 36, 38, 40.
†References 1, 2, 6, 10, 22, 35.

breve, *Bifidobacterium infantis*, *S. thermophilus*, *L. acidophilus*, and *Saccharomyces*, with varying dosages, administered with human milk, formula, or a mixture of human milk and formula feeding regimens.[22,24] The clinical trial data to support benefit for probiotics to prevent late-onset neonatal sepsis is also emerging.[40] Earlier clinical trials did not convincingly show benefit for probiotics to prevent sepsis, but more recent clinical trials have shown a significant positive effect. In one recent report, a synbiotic preparation containing probiotic *L. plantarum* and prebiotic fructo-oligosaccharide, administered to neonates with birth-weight greater than 2000 g, significantly reduced the incidence of sepsis syndrome, culture-positive sepsis, and mortality associated with sepsis in neonates.[31] It also had a beneficial effect by reducing lower respiratory tract infection requiring antibiotic treatment in infants enrolled in the study.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome and Cancer

Probiotics and prebiotics also are being applied in resource-poor and disadvantaged countries to reduce duration of diarrhea, improve gut function, and prevent bacterial vaginosis.[7,27] In addition, some studies suggest probiotics may improve well-being in human immunodeficiency virus (HIV)-infected patients and even reduce the risk for HIV transmission.[27] However, challenges to scientific study and implementation of proved clinical efficacy in resource-poor settings in developing countries include lack of infrastructure and funding to execute appropriately designed clinical trials, as well as provisions to make clinically proved probiotic and prebiotic products available at affordable prices to patients in developing countries. Research interest in evaluating the ability of probiotics and prebiotics added to diet to prevent or reduce incidence of various cancers is evolving, but at this time, there is no proved benefit for probiotics or prebiotics to prevent or treat cancer.[38]

SAFETY OF PROBIOTICS AND PREBIOTICS IN INFANTS AND CHILDREN

Prebiotics and probiotics appear safe for healthy infants over 5 months of age and healthy children of all ages.[38] In developing countries, prebiotics, probiotics, and synbiotics offer great potential for prevention of serious and potentially fatal bacterial illnesses and diarrheal illnesses in infants and children. However, the safety of administering probiotic products containing live microorganisms in high-risk or special patient groups requires careful consideration and caution should be used when they are considered for treatment in special or immunocompromised hosts.[38] Probiotic sepsis and other serious infections caused by probiotic microorganisms, including neonatal sepsis and meningitis, have been documented in patients at risk, including immunocompromised patients, ill preterm and low-birth-weight neonates, and children with intestinal disorders, short gut, and indwelling catheters.[35,36] Therefore, the potential risk for probiotics and prebiotics must be carefully balanced with the potential benefit in these patient groups.

CHAPTER 243

Health Care–Associated Infections

W. Charles Huskins • Julia Shaklee Sammons • Susan E. Coffin

Health care–associated (nosocomial) infections are infections that occur as a consequence of health care. Many of these infections are associated with the use of modern invasive devices and procedures that breach normal host defenses to allow microbial invasion. Other infections are due to exposure to pathogens in the health care environment, which are transmitted from colonized or infected persons or from contaminated objects and surfaces, water, or air or occur in persons with compromised immune systems or who are particularly susceptible to infection, such as preterm infants. Finally, health care–associated infections may occur in persons delivering health care (i.e., occupationally-acquired infections in health care providers).

HISTORICAL ASPECTS

The history of health care–associated infections and their control is tightly linked to developments in institutional medical care.[595] Although not broadly recognized, efforts to study and prevent infection among hospitalized children have contributed significantly to the development of infection control and prevention efforts in general.

Semmelweis' classic studies of puerperal fever in the Vienna Lying-In Hospital in the mid 1800s provided insights into the etiology and prevention of perinatal infections in neonates, not just their afflicted mothers.[596] Children also suffered greatly from the epidemics of contagious diseases that spread through hospitals during the 18th and 19th centuries.[229] This problem lead to the opening of wards and entire hospitals designated for the treatment of patients with infectious diseases in the early 20th century.[595] By the mid-20th century, a number of interventions had been developed to minimize the spread of contagious diseases in hospitals, including use of quarantine areas for new admissions, confinement of each child in an individual cubicle, creation of cohorts for patients admitted during community epidemics, use of masks by persons caring for patients, exclusion of visitors, strict control of the health of nurses and physicians caring for the patients, and implementation of exhaust fans to prevent airborne transmission of measles and varicella.[68,83,281,391,404]

Outbreaks of *Staphylococcus aureus* infection in hospitalized infants had been documented in the late 1800s and early 1900s,[97,341] but the pandemic of *S. aureus* infections that plagued hospitals in the 1950s and 1960s drew special attention to the impact of infections caused by this organism. Outbreaks of staphylococcal disease were particularly devastating in neonatal nurseries, where epidemics caused by specific phage types caused substantial morbidity and mortality.[586] The seriousness of the hospital-acquired staphylococcal infection problem spawned more comprehensive efforts to document the impact and consequences of hospital-acquired infections[562-564] and served as the impetus to develop organized infection control programs, particularly in Great Britain (with its tradition of infection control sisters) and North America.

In 1970, a hospital-acquired infection surveillance and control program was established at Children's Hospital in Boston and data were reported to the nascent National Nosocomial Infections Study at the Centers for Disease Control (CDC).[234] The study emphasized the association of hospital-acquired infections with exposure to invasive devices and procedures. Additional epidemiologic studies of infections in pediatric patients cared for in intensive care units (ICUs) during the 1970s and early 1980s strengthened the association between the use of invasive devices and procedures and hospital-acquired infections.[252,287,298,417]

Advances in viral diagnostics in the 1970s led to greater appreciation of the importance of viruses as a significant cause of hospital-acquired infections, particularly in pediatric patients.[673,704] Spread of respiratory and gastrointestinal viruses, especially respiratory syncytial virus (RSV) and rotavirus, was documented to be a severe problem on pediatric wards.[185,270,447,569,707]
